For delirious patients who are not experiencing alcohol or sedative withdrawal, benzodiazepines are avoided because they may exacerbate delirium and increase the risk of falls. Antipsychotic medications are the most studied class of drugs for delirium treatment. In non-ICU patients, the efficacy of these drugs is unclear, and review studies show no effect on delirium severity, symptom resolution, or mortality. Similarly, studies of patients in ICU indicate no significant treatment effects of antipsychotic medications on the duration of delirium, hypoactive/hyperactive delirium, or the number of days alive with/without coma. Other agents such as melatonin, ramelteon (a melatonin receptor agonist), and cholinesterase inhibitors have been suggested for delirium treatment, but there is limited consistent evidence supporting their use. However, expert consensus does support a limited role for drugs in the treatment of delirium, especially in patients with severe distress

For psychotic and behavioral symptoms, haloperidol, a typical antipsychotic, has been used due to its availability (it can be dosed orally and intravenously delivered) and, when dosed appropriately, has minimal adverse effects. It does not cause significant hypotension, is not anticholinergic, does not depress respiration, and does not cause or impair glucose regulation. The risk of QTc interval prolongation is minimized by staying within dosing guidelines and adhering to recommendations regarding QTc interval checks. Before haloperidol is initiated, a baseline QTc interval is obtained. If the interval is 450 ms or greater in a male or 470 ms or greater in a female, intravenous haloperidol should not be used. Any patient whose QTc interval is prolonged beyond 25% of baseline during treatment should have haloperidol discontinued. There is evidence that intravenous haloperidol is less likely to cause extrapyramidal symptoms than oral doses of haloperidol.

A conservative but usually effective dosing schedule for an older adult delirious patient is as follows: haloperidol 0.25 mg to 0.5 mg intravenously every 8 hours on a scheduled basis, and 0.25 mg to 0.5 mg intravenously every 6 hours as needed to keep agitation and psychotic symptoms under control. If oral dosing of haloperidol is used, higher doses are given (e.g., 0.5 mg to 1 mg by mouth every 8 hours and 0.5 mg to 1 mg by mouth every 6 hours as needed). Younger patients may require and tolerate higher doses of medication. How long the acute dose of haloperidol is maintained depends on how the patient responds clinically. If the patient becomes calm and psychotic symptoms lessen within the first 12 to 24 hours (as usually happens), this dose of haloperidol is continued for 2 to 3 days and then is tapered over the next 2 to 3 days. If the patient does not become calm within this time frame, consideration should be given to a missed or inadequately treated medical condition prolonging delirium. In this case, haloperidol would likely be continued for a longer period.

Atypical antipsychotic medications have been shown to be just as effective as haloperidol in controlling symptoms of agitation and psychosis in delirious patients. These medications are generally well tolerated when used for acute episodes of delirium. One limitation is that they are given orally rather than intravenously.

The two atypical antipsychotic agents which are most commonly used for delirium in older adult patients are risperidone and quetiapine, with dosing schedules as follows:

Risperidone 0.25 to 0.5 mg twice daily on a scheduled basis and 0.25 to 0.5 mg every 6 hours on an as-needed basis.
Quetiapine 25 mg at bedtime to 25 mg twice daily on a scheduled basis and 25 mg every 6 hours on an as-needed basis.

An 84-year-old man was admitted from home with acute coronary syndrome. Medical history was significant for coronary artery disease, myocardial infarction, left carotid endarterectomy, chronic renal insufficiency, and renal cell carcinoma. He underwent three-vessel coronary artery bypass grafting. On the first postoperative day, he was noted to be irritable, combative, and confused. He told his family that he was brought to the hospital for “experimentation” and had persistent tactile hallucinations of leaves and other objects in his mouth. Nighttime restlessness progressed to nocturnal insomnia and agitation. The patient had marked fluctuations in alertness during the day, with worsening agitation in the evening hours. During his agitated episodes, he pulled out his intravenous line several times. During a period of relative lucidity, an Mini-Mental State Examination (MMSE) was performed, and he scored 10/30. A psychiatric consultant recommended 0.5 mg of haloperidol orally every 8 hours on a scheduled basis for symptomatic treatment of his hallucinations and agitation. Medical complications (which included dehydration, atrial fibrillation, hypotension, and pneumonia) were managed as they arose. Although agitation and psychotic symptoms were improved, the patient required intermittent one-to-one observation by staff. After 7 days, his mental state began to improve as his medical condition stabilized. He was discharged on postoperative day 17 with some residual memory problems and insomnia but without evidence of psychotic symptoms or agitation.

FUTURE DIRECTIONS AND COVID CONSIDERATIONS

Despite progress over the years in understanding delirium, we still need more studies to elucidate the neuropathology of delirium, which can aid in preventing and treating delirium. *Animal models* could be helpful in understanding the underlying pathophysiology of delirium. Studies have looked at the role of interleukins, neurotransmitters, hypoxia, and brain pathology on delirium—but more studies are needed. An animal model could also be helpful in testing preventive or treatment strategies. Understanding pathophysiology may aid in devising pharmacologic targets. More studies of pharmacologic agents are needed to help with delirium prevention or treatment, including psychotropics that have limited evidence but continue to be used in multiple settings. Dexmedetomidine has also been looked at in the prevention or treatment of delirium in postoperative patients and should be explored further. Different approaches to sedation for surgery also are promising areas for investigation. In particular, using light sedation, where possible, seems to be less likely to cause delirium.

COVID-19, the coronavirus disease caused by severe acute respiratory syndrome coronavirus 2 (SARS-Cov-2), has also been implicated in causing high rates of delirium (up to 79.5% in ICU settings in the general population and up to 40% in non-ICU hospitalizations in older adults). There is limited evidence to elucidate the pathophysiologic role of COVID-19 in the development of delirium, but multiple mechanisms have been implicated, including systemic inflammation and/or direct brain entry of the virus. During the COVID-19 pandemic that arose in 2020, there were fears that best practices for delirium management would be compromised due to quarantine restriction requirements for inpatient care. Particularly early in the pandemic, shortages of personal protective equipment (PPE), changes to staff hierarchy and priorities, and restricted physical bedside presence affected adherence to delirium preventative protocols. These changes may have favored increased use of sedation and prolonged use of already limited ventilator resources. Early reports of COVID-19 cohorts suggested more widespread use of benzodiazepines for sedation and that COVID-19 patients often developed a severe delirium phenotype. At the present time, little is known about the impact of possible deviations from usual delirium management protocols on the course of COVID-19 delirium in older adults.

Clearly, more research is needed to fully understand the impact of the virus on the geriatric population.

Another area requiring future research is evaluating methods of improving the quality of life following delirium, as delirium is associated with functional decline and worsening disability in older adults. A collaborative approach to delirium prevention needs to be advocated with a focus on delirium prevention/treatment protocols. Strategies like the ABCDEF bundle and HELP protocol have shown benefits in decreasing delirium, but more studies of interventions that can help prevent or treat delirium are needed. Improved approaches to the prevention and treatment of delirium are needed to limit impairments and adverse outcomes on the physical, cognitive, and psychological functioning of older adults.

55.3h Schizophrenia and Other Psychotic Disorders

Carl I. Cohen, M.D., and Paul D. Meesters, M.D.

Over the past century, the vast majority of schizophrenia studies have primarily involved young adult patients, and only about 1% of the literature on schizophrenia is dedicated to issues of older adults. In this chapter, we examine early-onset and late-onset schizophrenia (LOS) in older adults and how they can be distinguished from other psychotic disorders in later life.

HISTORY AND COMPARATIVE NOSOLOGY

Emil Kraepelin’s description of “dementia praecox” as a disorder of progressive decline with onset during adolescence or early adulthood greatly influenced the subsequent conceptualization of schizophrenia. Nonetheless, Kraepelin later questioned the term *dementia praecox* after observing that the onset of this disorder was not limited to younger patients, nor was the course necessarily progressive. He used the term *paraphrenia* to describe a subset of patients with an onset of delusions and hallucinations that were primarily paranoid and with a better prognosis. This group of patients had several symptoms like those of dementia praecox but with less alteration of emotion and volition. Kraepelin was said to refer to paraphrenia as the “darkest area of psychiatry.”

Approximately 20% to 25% of patients with schizophrenia have an onset of the disorder after age 40. There has been considerable vacillation in diagnostic criteria regarding the age of onset. Martin Roth and colleagues introduced the idea that LOS could be a distinct entity after applying the term “late paraphrenia” to a group of patients with an onset of the disorder after the age of 60. Years later, the term “late paraphrenia” was included in the ninth edition of the International Statistical Classification of Diseases and Related Health Problems (ICD-9). The use of the terms “paraphrenia” and “late paraphrenia” led to some confusion because Kraepelin did not consider late age of onset a feature of paraphrenia, and paraphrenia is a more inclusive term and not synonymous with schizophrenia.

The early editions of the Diagnostic and Statistical Manual of Mental Disorders did not specify the age of onset criteria for schizophrenia. DSM-I and DSM-II included the category “Involutional Psychotic Reaction” for psychotic symptoms occurring during the involutional period, and DSM-II used the terms “involutional state” or “involutional paraphrenia” to describe a delusional condition with onset during the involutional period. In contradistinction, the DSM-III restricted the diagnosis of schizophrenia to onset before age 45, whereas the DSM-III-R included a late-onset category for initial presentations after age 44. The ICD-9 included the diagnosis of “Paraphrenia” and listed “Involutional Paranoid State” and “Paraphrenia, Involutional” as approximate synonyms. However, the ICD-10, DSM-IV, DSM-IV-TR, DSM-5, and the DSM-5-TR did not include separate diagnostic categories or criteria for LOS.

The omission of a late-life category is problematic since there is evidence that late-onset disorders, especially those arising after age 60, may differ clinically from earlier-onset cases. In 2000, an international expert group published a consensus report that proposed that schizophrenia be termed “Late-Onset Schizophrenia” and “Very–Late-Onset Schizophrenia-Like Psychosis” for disorders that have an onset between ages 40 and 60 and after the age of 60, respectively.

EPIDEMIOLOGY

Epidemiologic studies from the United States and the United Kingdom place the prevalence of schizophrenia at 0.6% to 1% in persons aged 45 and over and 0.1% to 0.5% in those aged 65 and over. Based on insurance claims data of persons aged 65 years and older, the prevalence estimates were 0.55% for men and 0.84% for women, with an overall prevalence of 0.71%. In the United States, by 2025, roughly three-quarters of a million people, or approximately one-fourth to one-third of all persons with schizophrenia, will be aged 55 and over; by 2060, their proportion may reach 40%. Worldwide, the number of people aged 60 years and older with schizophrenia will expand to an estimated 10 million people by 2050.

EARLY-ONSET SCHIZOPHRENIA

Schizophrenia typically develops in the second or third decade of life. Despite lower life expectancies than their age peers, increasingly more persons with schizophrenia are surviving into later life. It is estimated that nearly two-thirds of persons with schizophrenia aged 60 and over have an early-onset disorder.

Course and Outcome of Early-Onset Schizophrenia

There are several key points about course and outcome that have emerged in recent years that are relevant to the care of older adults with schizophrenia:

First, determining the outcome of schizophrenia can be a daunting task since it is dependent on definitions of the outcome, historical context, methods of assessment, diagnostic criteria, geographical settings, sociodemographic differences, age of onset, responsiveness to medications, and length of hospitalization Thus, Hegarty and colleagues looked at longitudinal studies of outcome in schizophrenia (all age groups) across the 20th century and found a mean improvement rate of 28% during the first quarter of the century, 49% in mid-century, and 36% in the last two decades.

Second, there is an increasing consensus that outcomes in schizophrenia are multidimensional and encompass clinical and social elements. A comprehensive view of outcomes in older adults should include symptoms, functionality, a combination of symptoms and functionality (“clinical recovery”), and positive health (“successful aging”) based on physical, social, and psychological well-being. The symptom outcomes include positive and negative symptoms (sometimes combined into “clinical remission”), depression, and cognitive functioning. The social functioning outcomes include community or social integration, adaptive functioning (e.g., activities of daily living), and quality of life (QoL).

Third, there is substantial heterogeneity in the outcomes of schizophrenia in later life. Despite scarce data, some findings suggest that the diversity seen in younger individuals might be even greater in older age. Long-term studies observing the symptoms and functioning in EOS suggest that the course of schizophrenia may not be as pessimistic as previously thought, and findings tend to challenge the notion implied in the term “dementia praecox.” Ten studies of hospitalized patients who were reinterviewed after hospital discharge (mean of 22 to 37 years postdischarge) conducted 30 to 50 years ago found recovery rates ranging from 12% to 55% based on a single assessment in later life. The investigators used varying diagnostic criteria and social indicators. Several cross-sectional studies conducted during the early part of this century found clinical remission rates ranging from 29% to 49% and clinical recovery rates of 22% in older adults with schizophrenia, nearly all of whom were living in community settings. However, longitudinal studies were less optimistic, with only about a quarter of persons displaying persistent clinical remission and about one-eighth attaining persistent clinical recovery. The latter was consistent with findings in young and mixed-age samples that found a median rate of clinical recovery of 13.5%.

Fourth, outcome measures are relatively distinct from each other and may need to be viewed as separate targets for intervention. A study in New York City of community-dwelling older adults with schizophrenia aged 55 and over who had early-onset disorder found that the shared variance among clinical remission, depressive symptoms, cognitive functioning, and community integration ranged from 0% to 22%, with a median value of 5%. The relative independence among outcomes suggests a variegated pattern of outcome and, consequently, the need for more targeted, personalized care. Indeed, when the investigators subsequently looked at five outcome measures over 52 months (remission, community integration, depression, cognitive functioning, and self-health), they found various combinations of favorable outcomes, as well as differences in the number of favorable outcomes, attained: 9%, 17%, 22%, 24%, 22%, and 6% had favorable outcomes in none, one, two, three, four, or all five outcome measures, respectively.

Fifth, although schizophrenia has been thought to be largely quiescent or have a steady end-stage in later life, recent longitudinal data shows this is not true. About two-fifths of persons fluctuate between being in and out of clinical remission, and between one-fourth and one-third of persons fluctuate between varying states of clinical recovery, depression, cognitive dysfunction, and community integration.

The final point is that the course in later life can be understood within the recovery model of mental illness. As noted above, while most persons do not achieve persistent clinical recovery, many display fluctuations in their symptoms and functioning. Based on longitudinal data from the NYC community study described above, Cohen and Reinhardt devised a five-tier taxonomy of late-life course trajectories among persons living in the community. On the two extremes, 12% showed persistent recovery, and 18% were unable to ever attain symptom remission or social integration. The remainder showed various combinations of remission and social integration. Hence, most older persons are in various states of recovery (“recovering”), and targeted approaches to address their specific clinical and social needs may advance their progress along the recovery continuum. Although the extremes of this continuum attract the most attention, most older patients with schizophrenia can be identified at some point in between these extremes, moving with time in one direction or the other.

While a prediction of the long-term course of the illness in an individual cannot be accurately made, the general factors associated with favorable outcomes include female gender, later onset of symptoms, less severe negative symptoms, and better premorbid functioning. However, with age, the strength of association between these variables and outcome weakens. Consequently, predicting a probable long-term course for schizophrenia patients is difficult. Apart from the relatively small group of poor outcome patients who worsen over time and who are largely found among long-term institutionalized patients in state hospitals or nursing homes (about 15% of all older adults with schizophrenia), most older community-dwelling persons with schizophrenia have been found to have a nondeteriorating course accompanied by fluctuations over time in individual outcome dimensions.

Symptom Dimensions of Outcome. In the previous section, we discussed some of the findings of hybrid or global measures of outcome, such as “clinical remission,” which combines various positive and negative symptoms, and “clinical recovery,” which combines remission and community integration. Below, we focus on key individual measures that comprise the dimensional framework in Section III of the DSM-5-TR. The DSM-5-TR authors contend that the dimensional assessment may assist with treatment planning, prognostic decision-making, and research on pathophysiology. In time, the dimensional model is expected to gain more traction in the care and research affecting older adults with schizophrenia.

POSITIVE SYMPTOMS. Long-term studies of outcomes have demonstrated that there is an improvement in positive symptoms with age. In the NYC community sample described above, roughly three-fifths of patients living in the community demonstrated favorable outcomes for positive symptoms. On 52-month follow-up, nearly half maintained persistently low or absent positive symptoms, and about one-third fluctuated between the presence and absence of positive symptoms.

NEGATIVE SYMPTOMS. Negative symptoms are thought to predominate the clinical picture of schizophrenia in later life. However, estimating negative symptoms in older schizophrenia patients can be challenging, as the clinical picture is often confounded by depression, demoralization, cognitive decline, medication effects, and poverty. The few studies of negative symptoms in community-dwelling older adults found prevalence rates of between one-quarter to one-half of the sample. Notably, longitudinal data from the New York City sample found that slightly over two-fifths of people fluctuated between the presence and absence of negative symptoms. Thus, contrary to earlier notions of schizophrenia progressing to a “burnt-out” state in later life, negative symptoms do not typically dominate the clinical picture, appear to be no higher than in younger schizophrenia populations, and fluctuate more than positive symptoms over time.

COGNITION. It is well established that older adults with schizophrenia have more cognitive deficits than their age-matched peers, with levels of cognitive deficits being nearly two standard deviations below control participants. Rajji and coauthors found that compared to healthy controls, persons with schizophrenia, aged 19 to 79, had lower scores in overall cognition and each cognitive domain except for social cognition. However, the rate of decline across the age groups was similar to that observed in the healthy control groups. Consequently, schizophrenia is no longer viewed as a neurodegenerative disorder (“dementia praecox”) but rather as a neurodevelopmental disorder in which deficits arise around the time of onset and do not progress beyond the expected effect of aging. While the rate of cognitive decline in schizophrenia may be similar to age-matched controls, the pre-existing deficits accrued at disease onset result in an earlier crossing of the diagnostic threshold into a major neurocognitive impairment (dementia).

Within-group longitudinal data of middle age and older adults with schizophrenia in the community showed considerable heterogeneity: a majority of persons seemed to be cognitively stable; however, about one-fifth of persons showed a more rapid decline, and one-fifth showed improvement, often rising from dementia to near-normal levels. Worse cognition (global and/or domain-specific) is strongly associated with diminished functional competence and community adaptation; more modest correlations have been found with older age, female gender, lower education, living in an institution, longer duration of illness, earlier age of onset, and higher levels of positive and negative symptoms.

Several recent epidemiologic studies have found prevalence rates of dementia diagnosis in persons with schizophrenia of 2 to 20 times that of their age peers, although the actual prevalence rates ranged from 1.8% to 64%, with rates of 70% at age 80 in one study. Friedman and coinvestigators found accelerated cognitive decline experienced by chronically institutionalized persons with schizophrenia beginning at age 65, but the decline in cognition was substantially less than in Alzheimer disease (AD). Patterns of decline, neuropathology, and polygenetic findings did not resemble those of AD, even among more chronically hospitalized groups. Rajji and associates’ review of older schizophrenia patients concluded that the findings of cognitive decline at age 65 found in institutionalized persons do not seem to apply to those who have been living in the community.

The fact that the course of decline and the underlying neuropathology differs from AD and that as many as one-fifth of persons show substantial improvements in cognition over time suggests that rendering a diagnosis of a major neurocognitive disorder may be inappropriate. As in the case of depression described below, the employment of the dimensional perspective described in the DSM-5-TR may help resolve these thorny diagnostic issues.

DEPRESSION. Among the studies on depression in older adults with schizophrenia, prevalence rates of depression ranged from 11% to 75%, depending on the severity criteria that were used. At all levels of depression, the prevalence was significantly greater than their age peers in the general population, although rates were similar to those of younger persons with schizophrenia. Because there is a substantial minority of persons who do not experience depression, it may be inappropriate to consider depression to be a core feature of the disorder, although it is a common feature with prevalence rates that remain high throughout the lifespan. Longitudinal data from the New York City sample showed that persistent depression (defined as the presence of syndromal or subsyndromal depression) occurred in 44% of persons, 30% remained persistently nondepressed, and 26% fluctuated between depression and nondepression.

The potential for suicide remains high in later life. Among depressed persons aged 40 and over with schizophrenia, 23% had current suicidal ideation, and 49% had made a previous attempt. In another study that included depressed and nondepressed persons with schizophrenia aged 55 and over, 13% had current suicidal ideation, and 30% had made a suicidal attempt during their lifetime.

Social and Adaptive Functioning

COMMUNITY INTEGRATION AND SOCIAL FUNCTIONING. Social functioning is a critical outcome indicator. Social functioning refers to the ability to establish and maintain relationships with friends and family as well as to undertake work and leisure activities. Adaptive functioning refers to the ability to function independently. A review by Meesters and colleagues concluded that the majority of older schizophrenic patients are well behind their healthy age-peers in various aspects of social and adaptive functioning, such as social roles, social support, and social skills. At the same time, considerable heterogeneity among patients can be found, and cognitive functioning had a major impact on social functioning, outweighing clinical symptoms. Other factors associated with better adaptive functioning include fewer negative symptoms, better physical health, and independent living. Long-term studies indicate that social functioning often improves in older schizophrenia patients, although, as with other domains, there may be movement in favorable and unfavorable directions over time.

A more recent body of work has focused on community integration in schizophrenia. Community Integration can be conceptualized as a "normalization" of functioning in society and comprises assessments of functioning and perceived QoL within several dimensions, viz., independence, physical, psychological, and social integration. In a cross-sectional study in New York City, a community comparison group of older adults had roughly twice the level of high community integration than those with schizophrenia (41% vs. 23%). In a longitudinal study using the same sample, 34% of schizophrenia persons fluctuated between high and low community integration, suggesting that there is a movement toward improved social integration in later life but also the potential for increased social isolation and diminished functioning.

QUALITY OF LIFE. QoL indicates an individual's self-perception of their position in life concerning their goals, expectations, and worries. It is an indicator of individuals' self-appraisal of their condition. Among older individuals with schizophrenia, lower QoL is associated with depression, positive and negative symptoms, cognitive deficits, financial strain, poor social support, and impaired social skills. Lower QoL may also predict suicidality. Although QoL indices are lower in older community-dwelling schizophrenia patients than their age peers matched for race and income, the absolute difference between the groups is small, and both scored in the moderate range of QoL and substantially higher than persons with chronic pain. Like other outcome measures, there is a fluctuation between good QoL and poor QoL. The New York City group found that 28% of persons moved between favorable and less favorable QoL outcomes, 40% had persistently favorable QoL, and only 32% had persistently less favorable QoL. Over time, many older adults with schizophrenia appear to find ways to adapt to their illness and, despite ongoing symptoms, value their QoL and find "wellness within illness."

In summary, the research data on the symptom and social outcome dimensions of schizophrenia in older patients provide some support for optimism in later life. However, based on recent longitudinal studies, we have a more nuanced understanding of the dynamics of various domains. Thus, as noted above, a favorable outcome in one category does not necessarily result in a favorable outcome in another category. This should lead to a more personalized care approach to treatment that will include a combination of biologic and psychosocial methods.

Medical Comorbidity and Mortality

Life expectancy is reduced by 15 to 20 years for people with schizophrenia. The mortality rate in schizophrenia is two to three times higher than in the general population, and this mortality gap has increased in recent decades. Although persons with EOS who live into old age should be considered to be survivors, the differences in mortality rates between persons with schizophrenia and their age peers persist into later life, perhaps even into their 80s. On the other hand, a review by Copeli and Cohen found that older adults with schizophrenia consistently showed lower age-adjusted mortality rates compared to middle-aged and younger persons with schizophrenia. While the mortality rate from suicides and accidents is elevated in older individuals with schizophrenia versus their age peers, natural causes of death account for the largest part of the reduction in life expectancy.

It is unclear as to why there are differences in mortality rates between older adults with schizophrenia and their age peers. Copeli and Cohen's review found inconsistent findings regarding differences in the prevalence of serious medical disorders between them. For example, compared to their age peers, older adults with schizophrenia had increased mortality rates and greater prevalence of respiratory diseases; no differences in mortality and prevalence of diabetes; higher mortality rates but no differences in the prevalence of cardiovascular disease; and considerable variability with respect to cancer, with incidence rates being equal or perhaps lower, but mortality rates being higher. Some of the differences in mortality can be attributed to lifestyle factors (e.g., poor diets, smoking, diminished physical activity), being in lower socioeconomic classes, and the impact of antipsychotic medications, especially second-generation antipsychotics. Some of the excess morbidity and mortality may be due to high rates of inflammation and oxidative stress reported among persons with schizophrenia. Moreover, they seem to be at risk for undetected or inadequately treated medical conditions that may be secondary to individual or systemic factors. A Danish Registry study found that persons with schizophrenia aged 70 and over did not differ from controls regarding chronic medical illnesses, but they were significantly less likely to receive medication for cardiovascular diseases; hospital admissions and the number of days hospitalized were equal to controls, but with significantly fewer general medical outpatient contacts. Finally, diminished insight regarding their symptoms and illness management may contribute to inadequate healthcare.

Biologic Features

Numerous neuroimaging cross-sectional studies support structural brain alterations in schizophrenia patients and controls. These include diminished gray matter in frontal, temporal, and postcentral cortical regions and increased ventricular size, and white matter reductions in the corpus callosum, although these findings have been inconsistent. Schnack and coinvestigators compared MRI scans for healthy subjects and persons with schizophrenia (age range 16 to 67 years) and found that there was an “accelerated” pattern of brain aging in people with schizophrenia at illness onset and during the initial 5 years; after that time, the rates of decline were comparable between the two groups, although the brain gap stayed constant.

Concerning neuropathology studies, a review by Centorino and Schultz concluded that postmortem studies have been even more mixed and complex than the neuroimaging studies, and no clear neuropathologic lesions have been demonstrated in older populations. Nguyen and colleagues’ review found that a majority of studies reported abnormal biomarker levels among older individuals with schizophrenia, including senescence-related indices of inflammation, telomere length, oxidative stress, metabolic health, gene expression, synaptic function, and testosterone, suggesting that schizophrenia is associated with aging-related biochemical abnormalities. About one-fourth of these studies observed age-related changes in schizophrenia, especially in markers of receptor/synaptic function and gene expression. Schizophrenia patients with greater disease severity and longer illness duration had higher levels of inflammatory and oxidative stress biomarkers and shorter telomere lengths. These studies must be interpreted cautiously because of inconsistencies in study designs, especially in the failure to control for potentially confounding variables such as smoking, substance abuse, exercise, diet, access to health care, and use of antipsychotic agents.

Treatment

There are only a few controlled studies assessing treatment approaches in older schizophrenia patients. Optimal treatment for older patients with schizophrenia will likely involve a targeted combination of pharmacology, nonpharmacologic therapy, and community-based approaches.

Somatic Approaches. Reviews of various open studies, along with the few controlled studies in older adults with schizophrenia, found somewhat mixed results for first-generation antipsychotics but more consistently favorable results with second-generation antipsychotics. Khan and colleagues provided an update on an earlier consensus paper and recommended risperidone (2 to 3 mg/day) as the first-line treatment for late-life schizophrenia; the second-line treatments are quetiapine (100 to 200 mg/day), olanzapine (5 to 15 mg/day), and aripiprazole (10 to 15 mg/day). For those with a late-onset disorder, the starting dose for antipsychotics should be ¼ of the typical adult dose, and the maintenance dose should typically be ⅓ to ½ of the adult dose.

Several studies found that estrogen treatment in postmenopausal women with schizophrenia resulted in diminished symptom severity. One controlled study suggested that citalopram may be effective for treating middle-aged and older schizophrenia adults with subsyndromal depression.

A literature review of electroconvulsive therapy (ECT) in older persons with schizophrenia identified six prospective studies and one case series; participants were between 49 and 96 years old. The authors concluded that bilateral ECT was effective as an acute and maintenance treatment in this population that had the onset of their illness earlier in life. ECT was not effective in those with very–late-onset psychosis, possibly due to the high prevalence of comorbid brain pathology other than schizophrenia. Transcranial magnetic stimulation and deep brain stimulation have not been studied systematically in the older age group.

The long-term use of antipsychotic medications has raised numerous concerns. Because of the pharmacokinetic and pharmacodynamic changes associated with aging, older people are more prone to the adverse effects of medications, for example, cardiovascular, orthostasis, metabolic, anticholinergic, extrapyramidal, sedation, falls, and neuroleptic malignant syndrome. In a middle-aged sample, higher lifetime antipsychotic dose years were associated with poorer cognitive performance. Gray matter volume decreases on MRI in people with schizophrenia are correlated with cumulative exposure to antipsychotic treatments, while no effects were observed for the duration of illness or illness severity.

Some older adults with schizophrenia may need little or no medication, either because symptoms have abated or because medication has been ineffective. Consequently, several writers have proposed trials to gradually taper or discontinue medications. Graff-Guerrero and coauthors' study of persons aged 50 and over found antipsychotic dose reduction was feasible in patients with stable illness and was accompanied by diminished adverse effects and improved illness severity measures. This may have been due to the lower therapeutic window of D2/3R occupancy that was needed in older persons (50% to 60%) than what had been reported in younger patients (65% to 80%).

Nonpharmacologic Approaches. Because many persons with schizophrenia, especially early-onset cases, do not make full recoveries with medication alone, a variety of nonpharmacologic strategies have been devised specifically for this population. The first generation of nonpharmacologic approaches focused on delivering group-based psychosocial skills training that enhances social cognition and perception, verbal communication, social skills, and interpersonal problem-solving skills. Random control studies found significantly favorable outcomes for several programs that have targeted middle-aged and older adults. The second generation of model programs focused on illness self-management and wellness techniques. Self-management strategies train older patients to assume greater responsibility for their physical health as well as improve coping abilities to deal with psychiatric stress.

There are emerging technologies that will enable older adults with schizophrenia to improve their health, age in place, and receive age-friendly care. These technologies encompass a variety of modalities, such as humanoid care robots, smart home systems and devices, personal devices, and software that enable telehealth connectivity. In-home sensing and monitoring devices address everything from medical needs such as fall detection and medication adherence to personal or “quantified self” measurements targeted to calorie and step counting, sleep quality, and air quality.

Community-Based Approaches. In older adult patients with chronic mental illnesses, Assertive Community Treatment (ACT) teams have engaged patients in treatment more successfully and had fewer dropouts from treatment versus comparison groups. Several model programs have combined collaborative care and case management strategies to address the medical and psychiatric issues facing many patients, as well as facilitate communication between the mental health team and the primary care providers. Collaborative care integrates mental health, primary care, and pertinent community supports and has the potential to ease the accessibility issues faced by older adults and to foster cross-discipline knowledge transfer to address complex clinical situations such as severe depression or suicidality. Case manager strategies typically use persons with clinical backgrounds to provide guidance, counseling, and skills training to older clients concerning psychiatric and physical health. They can also assist in guiding more appropriate care by primary care providers and enhance interdisciplinary communication.

LATE-ONSET SCHIZOPHRENIA

Epidemiology

A review of schizophrenia in later life found that slightly less than one-quarter of patients with schizophrenia had an onset of the disorder after age 40, with 13% in the fifth decade of life, 7% in the sixth decade, and 3% in later decades. A Dutch case-register study reported a 1-year prevalence rate of 0.55% for schizophrenia in persons over age 59 years, of which 64% had EOS and 35% had LOS. These figures suggest that the loss of early-onset individuals (to death or recovery) may be partially compensated by the influx of cases with a later onset. The epidemiologic study of LOS is complicated by several factors, including the use of various definitions of “late onset,” uncertainty in the determination of the age of onset, and questions regarding a correct diagnosis.

LOS affects women between 2 and 10 times more often than men. The robustness of this finding, coupled with the higher incidence rates of EOS in men, has led to the hypothesis that estrogen-mediated dopaminergic inhibition may protect younger women from schizophrenia, whereas the relative estrogen deficiency associated with menopause may be related to the increased incidence of LOS in women. A majority of treatment interventions with estrogen in postmenopausal women with schizophrenia have shown an improvement in symptoms. However, the incidence of schizophrenia is still considerably higher in younger versus older women.

Thus, an alternative hypothesis is that older men may be protected in some way.

The precise etiology of LOS, with an age of onset of between 40 and 60, and very late-onset schizophrenia-like psychosis (VLOS), with onset over age 60, is largely unknown. The International LOS Group concluded that schizophrenia with onset in middle age is a neurodevelopmental disorder and that differences with EOS are more of degree than of kind. The group also postulated that VLOS had some features that suggested a neurodegenerative component, including more brain abnormalities and neuropsychological deficits. A potential problem with this tripartite classification system is its reliance on age rather than clinical presentation, and some persons over 60 can resemble earlier-onset cases.

Overall, symptom presentation in EOS and LOS is more similar than different. Most studies have found that patients with LOS did not differ significantly from those with EOS regarding the severity of positive symptoms, although a large study by Vahia and colleagues found that late-onset patients had less severe positive symptoms and general psychopathology. This study also found that both groups had similar negative, depressive, and deficit symptoms.

Both EOS and LOS have cognitive deficits at presentation. Most studies have reported that, like EOS, cognitive deficits in LOS generally remain stable over time. There is less consensus on the nature and severity of these cognitive deficits. Some studies have reported fewer severe cognitive deficits in LOS as compared to EOS; others have found no differences in severity. No consistent biologic markers of schizophrenia with a later onset have been identified, although one study found raised C-reactive protein concentrations in people with LOS and VLOS.

A review of neuroimaging studies that compared EOS and LOS found differences in 8 of 10 studies, but there were inconsistencies across the studies. Similarly, measures of event-related brain potentials and neurofibrillary tangle densities found no differences between EOS and LOS groups.

Limited data exist specifically examining functioning in LOS. Patients demonstrated significantly greater disability in various areas of social functioning compared to healthy controls. Although marriage rates are higher in persons with LOS compared to EOS, social isolation was greater when comparing LOS patients to the general population. While some studies found that LOS was less frequently associated with a family history of schizophrenia than EOS, a more recent study reported no appreciable differences. Familial association of schizophrenia appears to be more common in EOS and LOS than in VLOS.

While differences between early-onset schizophrenia and LOS are more subtle, VLOS is a special case. VLOS is rare, with a reported annual incidence of 27 per 100,000 men and 48 per 100,000 women. Previous findings examining age have been mixed, showing both increased and decreased VLOS incident rates with advancing age. The clinical presentation of VLOS includes many striking features. One of them is a high prevalence of partition delusions. In this type of delusion, a person is convinced that people, objects, or radiation can pass through impermeable structures (walls, windows, doors). Hallucinations often involve multiple sensory domains (e.g., auditory, visual, tactile, olfactory). Formal thought disorders and negative symptoms, core symptoms of schizophrenia at a younger age, are infrequent, which has further fueled criticism of whether VLOS should be considered as a subgroup of schizophrenia. Mood disruption often occurs in VLOS, but adequate research to confirm this is lacking. Patients tend to be agitated and combative about their paranoid psychotic experiences.

The pattern of cognitive dysfunction is a focus in the debate on whether VLOS is a primarily neurodegenerative disorder. Nonetheless, like schizophrenia starting at a younger age, cognitive dysfunction in VLOS affects mainly frontal-subcortical cognitive domains. Memory disorders relate to learning new information, but retention of information is usually unaffected. This finding stands in contrast to the retention disorders that characterize cortical dementias like AD. Limited data exist on the longitudinal course of cognitive dysfunction in VLOS, and most studies had relatively short follow-ups. An often-cited Australian study that assessed cognition over 5 years found conversion to dementia in 9 of the 19 subjects. However, these findings were criticized for possibly including patients with early-stage dementia with psychotic features. Neuroimaging studies in VLOS have been very few but did not convincingly demonstrate a neurodegenerative substrate. Genetic factors have not been implicated in the etiology of VLOS.

In clinical practice, patients for whom VLOS is considered a differential diagnosis constitute a heterogeneous population, with only a proportion of them developing dementia with time. Like LOS, in VLOS, there is a broad differential diagnosis with other disorders involving psychotic symptoms in later life. A more conclusive diagnosis of VLOS, therefore, can be made only after a sufficient follow-up period.

Table 55.3h–1 provides an outline of the features that distinguish the three categories of schizophrenia.

Course and Prognosis

The course of LOS is often chronic but may be interrupted by partial remissions and exacerbations. Most studies have reported that in LOS, as in EOS, cognitive deficits tend to remain relatively stable over time, apart from changes associated with normal aging. The overall prognosis of LOS may be better than that of EOS. Patients may be quite responsive to antipsychotics used in lower doses. However, mortality rates, especially from suicide, exceed that in the general population and are probably comparable to those in EOS.

Treatment

Concerning LOS, a Cochrane report, updated in 2013, concluded that there is a paucity of trial-based evidence upon which to base guidelines for the treatment of LOS and that there is a need for good quality-controlled clinical trials. Howard and colleagues reported that a low dose of the antipsychotic drug amisulpride (100 mg) was effective and well-tolerated as a treatment for VLOS. Many of the pharmacologic and psychosocial recommendations for EOS can be applied to LOS, although expert guidelines suggest lower doses of antipsychotic medications may be needed in the latter.

Psychosocial treatment is a vital aspect of the management of LOS, and treatments specifically designed for older adults with schizophrenia, such as cognitive behavioral therapy and social skills training, have shown promise. The ability to engage patients who often lack insight into their disorder requires an assertive and multidisciplinary approach.

DIFFERENTIAL DIAGNOSIS OF PSYCHOTIC DISORDERS IN LATER LIFE

Making a diagnosis of schizophrenia in later life can be challenging. The onset of hallucinations and delusions in older adults can arise de novo or be associated with mood disorders, sensory deficits, polypharmacy, substance abuse, medical disorders, or dementia. The lifetime risk of developing psychotic symptoms in late life has been estimated to be up to 23%, primarily due to incident dementia. The prevalence of psychotic symptoms in noncognitively impaired older people has been estimated to be between 1% and 13.4%, with a median prevalence of 3.6%. One review study from Western Europe found the prevalence of psychotic symptoms among noncognitively impaired older adults increased with advancing age, so that rates were under 2% in persons aged 65 to 74, but 4% and 7% in those aged 85 to 94 and 95 to 104, respectively. The prevalence of psychosis in late-life in clinical populations is appreciable and is observed in 5% to 15% of geriatric psychiatry inpatients and up to 62% of nursing home patients. The clinician must be able to distinguish between "primary" psychosis (not attributable to other medical disorders) and "secondary" psychosis (attributable to other medical disorders), which account for 40% and 60% of cases in older adults, respectively. It is essential to obtain an accurate history and appreciate the time course of the disorder. Table 55.3h–2 lists the principal etiologies and time trajectories of psychotic disorders in older adults.

Table 55.3h–1.
Features Differentiating the Schizophrenia Subcategories

	Early-Onset Schizophrenia (EOS)	**Late-Onset Schizophrenia (LOS)**	**Very–Late-Onset Schizophrenia-Like Psychosis (VLOS)**
Age of onset	<40	40 to 60	>60
1-year prevalence among persons age 60+ (Dutch Catchment Area Study)	0.55%	0.14%	0.05%
Gender	Male = Female	Female > Male	Female >> Male
Family history of schizophrenia spectrum disorder	Present	Present	Absent
Cognitive decline	Deficits present at illness onset with age-related decline (stable vs. peers)	Deficits present at illness onset with age-related decline (stable vs. peers)	Substantial decline in a significant minority
Positive symptoms	▶ Severity of positive symptoms at onset but some improvement in later life ▶ Variety of positive symptoms ▶ Auditory hallucinations > visual hallucinations	Current level and characteristics of positive symptoms similar to older adults with EOS	▶ Lower severity of positive symptoms vs. EOS ▶ Visual hallucinations > auditory hallucinations

			▸ Other hallucinations such as tactile and olfactory are more common ▸ More somatic delusions ▸ More partition and persecutory delusions Auditory hallucinations with accusatory running commentaries
Negative symptoms	Present	Present	Absent
Thought disorder	Present	Present	Absent
Depression	Present	Present	Less common
Mortality vs. age peers	Higher	Higher	Higher
Antipsychotic dosage	May need higher dosages	Lower doses may be effective	Very low doses may be effective
Nonpharmacologic treatment	Psychosocial skills training; self-management techniques	No controlled studies	No controlled studies

Mood Disorder

Differentiating schizophrenia from mood disorder with psychotic features and schizoaffective disorder can be difficult because mood disturbances are common during the prodromal, active, and residual phases of schizophrenia. As described earlier, prevalence rates of cooccurring clinical depression have been found in up to three-quarters of older persons with schizophrenia, although mood symptoms may not meet the criteria for major depression. Furthermore, mood-congruent or mood-incongruent psychotic features may occur in major depression or bipolar disorder, although in both disorders, psychotic features tend to be more mood-congruent, for example, grandiosity, erotomania, special powers among bipolar individuals and delusions of poverty, guilt, sin, or physical illness in depressed persons. Auditory hallucinations occur less commonly in depression and may be vague or condemnatory. Catatonic features are more commonly seen in severe depressive disorders, and a history of mood symptoms may help to discriminate between conditions based on DSM-5-TR criteria. Mood disorder with psychotic features beginning after 40 years of age is differentiated from LOS by its affective symptoms that precede psychotic symptoms.

Table 55.3h–2.
Causes of Psychotic Symptoms in Older Adults

Etiology	Primary vs. Secondary Psychosis	Prevalence Among Psychotic Disorders	Time Course
Affective disorders	Primary	38%	Weeks to months
Schizophrenia spectrum and delusional disorders	Primary	3%	Months to decades
Major neurocognitive disorders (all types)	Secondary	40%	Months to years
Medical disease	Secondary	7%	Days to months
Delirium	Secondary	7%	Hours to days
Drug toxicity (substance abuse/medications)	Secondary	4%	Hours to months

Schizoaffective Disorder

It can be tricky to distinguish schizophrenia with depressive symptoms from schizoaffective disorder. The key difference is that in schizoaffective disorder, a *major* mood disorder must be present. The mood symptoms must occur simultaneously with the active-phase symptoms of schizophrenia, and they must be present for a substantial proportion of the total active and residual periods of the illness. Additionally, delusions or hallucinations must be present for at least 2 weeks in the absence of prominent mood symptoms. If the mood symptoms have a duration that is brief in relation to the total duration of the disturbance or do not meet the full criteria for a major depressive disorder, manic disorder, or mixed episode, then a diagnosis of schizoaffective disorder cannot be made. In the DSM-5-TR, clinicians must determine if a major depression has been present for a “majority” of the active and residual portions of the schizophrenia illness. Thus, clinicians must decide based on the life history of the illness, whereas previously, clinicians tended to look at discrete episodes. For geriatric psychiatrists, accurately determining what proportion of a 30 or 40-year illness involved major depression or manic symptoms is nearly impossible. Also, over the course of the illness, some older persons who had major depressive symptoms may attain persistently lower levels of depression, and consequently, they may no longer be considered to have schizoaffective disorder. The DSM-5-TR acknowledges the potential transience of the diagnosis and that some individuals will convert from schizoaffective disorder to another disorder as mood symptoms become less prominent. For these reasons, the DSM-5-TR states that there is growing evidence that schizoaffective disorder is not a distinct nosologic category.

Delusional Disorder

Delusional disorders can generate diagnostic conundrums. Persecutory, somatic, or erotomanic delusions in the older adult patient are typically secondary to another neuropsychiatric disorder (e.g., schizophrenia, mood disorder, or dementia); however, occasionally, a primary delusional disorder is implicated. Delusional disorders are rare in later life, with a prevalence rate of 0.03% to 0.04% and a lifetime risk of between 0.05% to 0.46% (the DSM-5-TR estimates the lifetime prevalence at 0.2%), which is well below lifetime risks for schizophrenia and bipolar illness. Delusional disorders usually first appear in the middle to late adulthood. The overall prevalence of delusional disorders is slightly higher among women than among men, and the average age of onset is earlier for men (40 to 49 years) than for women (60 to 69 years). There are no clear neuroanatomical changes associated with delusional disorder. There is mixed evidence that hearing or visual abnormalities might play a role in the development of delusional disorders. Family, twin, and adoption studies have suggested that a close association between delusional disorder and schizophrenia is unlikely, although rates of familiar schizophrenia may be higher than in the general population.

Delusional disorder is differentiated from schizophrenia by a lack of prominent hallucinations and an absence of deterioration in areas of functioning outside the delusional scope. The delusions are necessarily nonbizarre and involve situations that may occur in real life, such as theft, suffering from a disease, or spousal infidelity. For example, delusions that are seen commonly in older adult patients include skin infestation by insects; that internal organs are cancerous; that the person is being spied on, followed, or poisoned; and that the spouse is unfaithful. One study found that nearly half of patients had persecutory delusions. Consequently, a delusional disorder may be difficult to differentiate from schizophrenia with prominent paranoid ideation, especially in instances in which disorganized speech, disorganized behavior, or flat or inappropriate affect are less prominent. Nonetheless, the presence of auditory hallucinations or bizarre delusions seen in schizophrenia should differentiate the disorder. Furthermore, poor psychosocial functioning in delusional disorder is directly related to the delusional beliefs themselves, but marital and social functioning may be compromised. While subtle cognitive deficits may be found, intellect is generally maintained. Like schizophrenia, the course of the disorder varies among those afflicted, with perhaps one-third experiencing remission and two-thirds a prolonged course. Many avoid treatment, although among those who take antipsychotic medication, improvement has been reported in more than four-fifths of patients.

Psychosis Associated With Cognitive Disorders, General Medical Conditions, or Delirium

A patient who presents with psychotic symptoms after the age of 40, particularly if the symptoms develop after the age of 60, requires a thorough evaluation for underlying medical and neurologic disorders. Dementia is a common disorder in older adult persons, and 50% to 60% with a diagnosis of dementia of the Alzheimer type may experience psychotic symptoms at some point during their dementia. Delusions in AD tend to be nonbizarre, episodic, and preceded by cognitive decline. Typically, delusions in AD involve someone stealing from them or entering their house. Visual hallucinations are more common in AD than in schizophrenia, while auditory hallucinations are less common. Other neurocognitive disorders such as Lewy body Dementia and Parkinson Disease with Dementia may have higher rates of hallucinations and delusions than AD, whereas vascular and frontotemporal dementias have lower rates of psychotic symptoms.

Psychosis due to a general medical condition is diagnosed from the history, physical examination, or laboratory tests that show the delusions or hallucinations are the direct physiologic result of a general medical condition. Metabolic disturbances and neurologic and endocrinologic disorders are the most common causes of psychotic symptoms.

The diagnosis of delirium is established through observation of an acute change in mental status. and is characterized by a fluctuating deficit in attention, with changes in cognition that are not better explained by another neurocognitive disorder. The diagnosis of delirium remains reliant on clinical acumen, despite multiple efforts to establish diagnostic biomarkers. Behavioral symptoms are very common during delirium, including hallucinations and delusions, sleep disturbances, aberrant behavior, and affective lability. Hallucinations and delusions are common in delirium, with prevalence rates ranging from 40% to 70% for hallucinations, which are more frequently visual, and from 24% to 79% for delusions, which are more commonly paranoid types.

Substance-Induced Psychotic Disorder

About half of persons aged 65 and over drink alcohol, and one-fourth of those aged 85 and over continue to drink. Illicit drug use has been estimated at 10% to 15% of persons aged 50 to 64 and 5% among those aged 65 and over. At least one prescribed medication is taken by 87% of older adult adults, and 38% take five or more medications; about two-fifths use over-the-counter medications. These older adults are at greater risk for adverse effects because of polypharmacy, changes in metabolism and neuroreceptor sensitivity, and comorbid physical and neurologic disorders. Several different substances, such as amphetamines, cocaine, and phencyclidine, can produce symptoms like those of schizophrenia, such as delusions, hallucinations, or a mixture of positive and negative symptoms. Many substances can induce psychotic symptoms during withdrawal states, that is, benzodiazepines, barbiturates, and alcohol. Ideally, substance-induced psychotic disorders would be differentiated from schizophrenia after a period of abstinence; however, other evidence, such as whether the psychotic symptoms appear to be exacerbated by the substance and decrease when it has been discontinued or whether the psychotic symptoms have been instigated and maintained by the substance use, need to be considered.

55.3i Personality Disorders

Marc E. Agronin, M.D.

Multiple normative and pathologic changes during the aging process affect personality, and these same forces apply to the consideration of personality disorders in late life. These disorders represent a heterogeneous array of chronic affective and behavioral disturbances that cause enormous personal and interpersonal distress and pose significant challenges to clinical management, especially in the setting of comorbid medical and psychiatric conditions. Changing and inherently limited diagnostic schemes combined with a general lack of previous study make it difficult to understand and plot the trajectory of a given personality disorder in late life. Clinical perspectives on personality stability versus change will vary depending on the methods of assessment. There is limited empirical evidence and a range of unsubstantiated opinions as to whether personality disorders persist with minimal or no change, convert into more age-appropriate forms with similar levels of pathology, or remit over time. Understanding all of these factors is critical to improving diagnosis and optimizing clinical management.

DEFINITIONS

Defining the concept of *personality* itself is key to a fuller understanding of personality disorders. According to the *Bantam Medical Dictionary*, personality is “an enduring disposition to act and feel in particular ways that differentiate one individual from another.” George Vaillant qualifies this definition, suggesting that the enduring aspects of personality, which he terms *temperament,* consist largely of various inherited elements such as personality traits and IQ. He bases this belief on longitudinal studies of core personality traits (e.g., extroversion, introversion) that have generally found stability with aging. On the flip side, Vaillant holds that elements of personality or *character* defined by adaptive styles can change significantly with aging, affected by both “environment and maturation.” Putting together both elements of stability and change, Henry Murray’s statement that “the history of the personality is the personality” is most helpful when considering aged individuals. Lacking accurate longitudinal data from an older individual’s younger days, the average clinician is forced to make decisions about personality functioning based on more recent history.

The distinction between normal and abnormal personalities is based largely on the expression of certain personality *traits* (as opposed to more acute psychopathologic symptoms) that are repeatedly associated with unhappiness, interpersonal conflict, and/or occupational dysfunction. Although everyone has a unique personality with relative strengths and weaknesses, the current diagnostic model requires the categorization of certain personalities as pathologic along the lines of various subtypes. This categorical model has been criticized for the ways in which it provides pejorative labels and obscures the richness of personality. In late life, it is particularly problematic given the large number of physical and psychosocial stresses that can distort an individual’s pattern of adaptation.

An alternative dimensional approach was proposed but not adopted in the *Diagnostic and Statistical Manual of Mental Disorders,* fifth edition (DSM-5). Personality disorders are defined in DSM-5 as chronic psychiatric disorders characterized by enduring and pervasive patterns of inflexible and maladaptive inner experiences and behaviors. These dysfunctional features are rooted in early development, deviate from cultural expectations, and lead to significant social and occupational impairment across several spheres of function: perception and interpretation of experiences, emotional expression, interpersonal relations, and impulse control.

There are 10 subtypes of personality disorders listed in the DSM-5 classification, grouped into three broad phenomenologic clusters: cluster A, the *odd* cluster, includes paranoid, schizoid, and schizotypal subtypes; cluster B, the *dramatic* cluster, includes antisocial, borderline, histrionic, and narcissistic subtypes; and cluster C, the *anxious* cluster, includes avoidant, dependent, and obsessive-compulsive subtypes. Depressive and passive-aggressive (or negativistic) personality disorders were two subtypes that were listed in the appendix of the *Diagnostic and Statistical Manual of Mental Disorders,* fourth edition text revision or DSM-IV-TR but are no longer included in DSM-5. Each personality subtype is defined by 8 to 10 diagnostic criteria, and an individual must meet a specified number of them in any combination in order to qualify for a diagnosis. Individuals may demonstrate a single disorder or a combination of maladaptive traits from several disorders. Individuals who have symptoms characteristic of a personality disorder in general, but do not meet the criteria for any specific disorder, may be diagnosed as having an *unspecified personality disorder.*

Although there are several designated pediatric categories for personality disorders, there are no equivalent, age-adjusted geriatric subtypes, despite growing evidence that changes in both personality and personality disorders in late life can lead to enduring but *different* patterns of personality dysfunction. However, when personality change results from physical damage to the brain from substance abuse or a medical condition, the term *personality change due to another medical condition* can be used (with the medical condition specified and then coded separately), with several designated subtypes: labile, disinhibited, aggressive, apathetic, and paranoid. Common causes of personality change include traumatic head injury, stroke, endocrine dysfunction, encephalitis, and Alzheimer disease.

EPIDEMIOLOGY

Community-based epidemiologic studies have found rates of personality disorders in adults ranging from 10% to 20%, with the 2001–2002 National Epidemiologic Survey on Alcohol and Related Conditions (NESARC) Data for 16,884 adults ages 50 and older yielding a rate of 10.7% for at least one personality disorder. Another set of NESARC data found a rate of 14.5% of one or more personality disorders in older adults. These rates increase two- to threefold in individuals being treated in both outpatient and inpatient psychiatric settings for comorbid psychiatric diagnoses, particularly major depression. For example, a study of 546 older adult psychiatric inpatient admissions found personality disorders in 13% of all patients, which increased to 24% of those diagnosed with major depression. In all studies, the method of diagnosis has produced variations in prevalence rates. Epidemiologic surveys and more impressionistic clinical diagnoses have generally found higher rates of personality disorders and yet a more limited spectrum of subtypes compared to criterion-based structured clinical interviews.

The most common personality disorders seen across late-life studies have been paranoid, avoidant, dependent, and obsessive-compulsive subtypes. The most common subtype in the NESARC data sets was obsessive-compulsive personality disorder at 6.5% to 7.6%, followed by narcissistic personality disorder at 3.9% and paranoid personality disorder at 2.5%. In late life, nearly two-thirds of those diagnosed with a personality disorder also meet the criteria for two or more subtypes or for the unspecified category. It is important to bear in mind that the lifelong course of specific subtypes will influence prevalence. For example, a decrease in the prevalence of antisocial personality disorder in late life no doubt results from increased rates of remission, death, institutionalization, and avoidance of psychiatric settings with age. Decreasing rates of other personality disorders in late life may be due to the fact that they are difficult to differentiate from other specific psychiatric diagnoses or may change in ways that obscure their recognition.

There are limited data on the prevalence of personality disorders in long-term care settings, due to the great difficulty obtaining longitudinal data, in addition to the challenge of interviewing individuals who may be suffering from varying degrees of cognitive impairment. One survey that based diagnoses on clinical interviews found that nearly 11% of a modest sample of nursing home residents had a primary or secondary diagnosis of personality disorder. An identical diagnostic rate was found in a sample of intellectually disabled adults older than 40 years who were admitted to a long-term care institution—although, in that study, the congenital diagnosis might call into question the personality disorder diagnoses.

A review of referrals to a nursing home found that 15% were for unspecified personality problems, although it is not clear how many of these individuals had actual personality disorders. Rates for personality disorder subtypes in long-term care facilities have not been established in any study.

DIAGNOSIS

In spite of the very specific diagnostic criteria provided by DSM-5, clinicians immediately encounter a plethora of diagnostic challenges when assessing older individuals. Sometimes the older personality, viewed from an ageist stance, is erroneously believed to be more dependent, stubborn, hypochondriacal, and less adaptive in the face of stress compared to younger personalities. Such an attitude may lead clinicians to view many disordered behaviors as normal in late life, preventing accurate diagnosis. At the same time, many clinicians might not consider the possibility of a personality disorder in an older patient or might be daunted by the large number of diagnostic criteria. As a result, these diagnoses are often deferred or merely lumped under an unspecified category. Lack of knowledge either of specific criteria or how to apply them in late life has been shown to create discrepancies between largely impressionistic clinical diagnoses and those determined through more rigorous structured interviews.

The criteria themselves foster misdiagnosis since they were developed for adults and do not take into consideration age-associated changes in lifestyle and behaviors that render many of them obsolete in later life. For example, the diagnosis of antisocial personality disorder includes criteria such as “repeatedly performing acts that are grounds for arrest,” “repeated physical fights or assaults,” and “consistent irresponsibility” with work or financial obligations. For an older person who is retired from work, residing in congregate living or a long-term care facility with limited mobility, or physically frail, these criteria will simply not apply. Diagnostic criteria for borderline personality disorder, such as self-injurious behaviors and self-damaging impulsivity with respect to spending, sex, driving, or eating, are also less applicable to older adults, who in general tend to be less impulsive. As of yet, there are no geriatric criteria that can be substituted, and attempts by clinicians to make diagnoses based on fewer criteria or to “age-adjust” other criteria threaten the very validity of the diagnosis. Several age-specific tools with reasonable accuracy have been developed to address evolving diagnostic symptoms, including the Gerontological Personality Disorders Scale. Researchers have also suggested that dimensional rather than categorical models may be more useful across ages.

Not surprisingly, an analysis of data from the National Epidemiologic Survey on Alcohol and Related Conditions, which studied over 43,000 individuals, found that young and old adults endorsed nearly 30% of personality disorder criteria differently, despite having equal degrees of personality dysfunction. The end result was that older adults were more likely to have schizoid and obsessive-compulsive personality disorder diagnoses, while younger adults were more likely to have avoidant and dependent personality disorder diagnoses. The same diagnostic criteria, then, yielded different disorders based on age.

Another diagnostic dilemma is the need for accurate longitudinal descriptions of a personality on which to base the diagnosis. Unlike symptoms of most other psychiatric disorders, which are readily reported or observed, personality disorder symptoms can be more difficult to elicit through self-report given their pejorative nature, and when observed, require repeated encounters across different settings to be accurate and reliable. Instead, clinicians often have to rely on clinical records, which typically lack longitudinal data, or on existing informants who can rarely provide critical information dating back to an older patient’s young adulthood.

An important caveat for any clinician attempting to make a late-life diagnosis is that personality dysfunction does not necessarily indicate a personality disorder. Significant, repeated, and sometimes devastating losses in late life, such as the death of a spouse or of a series of close friends, a chronic debilitating illness, chronic pain, physical disability, the loss of finances or livelihood, or the overall loss of personal attributes that once defined an individual (e.g., strength, beauty, athletic, or sexual prowess), can lead to severe adjustment reactions that mimic personality disorders. Without clear longitudinal information, it is difficult to determine whether a patient with pervasive dysfunctional interpersonal relations, for example, is demonstrating a lifelong pattern or a more recent reaction to life events. Many symptoms of major depression and generalized anxiety disorder overlap with depressive, negativistic, avoidant, and depressive symptoms of several personality disorders. Similarly, symptoms of persistent bipolar mania can mimic antisocial, narcissistic, and borderline traits. For this reason, personality disorder diagnoses are best deferred during episodes of acute psychiatric syndromes. Perhaps one of the most difficult decisions to make is whether changes in demeanor brought on by neurocognitive disorders and associated neuropsychiatric syndromes such as apathy are merely expressions of the underlying disorder or represent a true personality change.

CLINICAL FEATURES AND COURSE

Since its inception in 1952, iterative versions of the DSM have provided a heterogeneous and fluid array of personality disorder subtypes up until the more enduring categorization that appeared in the third edition of the DSM (DSM-III) in 1980. Despite the relative stability in the nomenclature since then, the DSM has never been clear on the course of personality disorders into late life, only suggesting that several remain relatively unchanged while others attenuate. The possibility of a late-onset personality disorder is not addressed in the DSM, aside from the diagnosis of a personality change disorder. Unfortunately, there are limited data on most subtypes, and current thinking rests largely on case studies.

For the clinician working with older adult individuals with known or suspected personality pathology, the main question is: What do these disorders look like in late life? Are they fundamentally the same as in previous years, or does aging change them in ways that either attenuate symptoms and cause remission or lead to similar degrees of pathology but with novel, age-appropriate manifestations? Consider the following clinical vignette.

Mr. L was an 82-year-old man who suffered from brittle diabetes, morbid obesity, and chronic obstructive lung disease. After his wife died, Mr. L was unable to manage his own care needs and had to be admitted to an assisted living facility (ALF). He was oxygen dependent and used an electric scooter to get around. Mr. L quickly established a reputation as a rude and aggressive man. He would badger other residents and staff in the elevator when they did not get out of his way quickly. He would make unrealistic demands of the waiters in the dining room and insult them when he did not get his way. He accused the nursing staff of deliberately withholding treatment after one of his medications went missing from his tray. Over time, the staff grew increasingly tired of his verbally abusive and disruptive behaviors and was afraid to help him since he often threatened to sue them for shoddy care. They described him as a difficult, paranoid, and hateful person.

These behaviors built into a crisis one day when Mr. L became enraged at a deaf resident standing in front of him in the elevator who could not hear him berating her for moving out of his way. He pushed her down and ran over her foot with his scooter, causing a serious skin laceration and bruise. He completely denied his actions, however, accusing the injured woman of deliberately feigning injury after blocking his scooter and getting bumped. He screamed at all staff who tried to intervene and threatened to kill anyone who got in his way. As a result, Mr. L was hospitalized involuntarily and not allowed to return to the ALF.

Additional information on Mr. L indicated that he had been an extremely aggressive but quite successful real estate broker as a young and middle-aged man. His daughter estranged herself from him due to his abusive behaviors, and his son limited his contact with his father, whom he described as arrogant, paranoid, and verbally abusive to those who disagreed with him. Mr. L's behaviors were chronic but seemed to have improved in the several years prior to his becoming ill, perhaps because his business success enabled him to get involved in several gratifying philanthropic endeavors. However, with the onset of illness and then the death of his wife, he could not cope with being dependent on others for help. He was completely unable to trust staff or forge stable relationships in the ALF and became increasingly angry, depressed, and paranoid. Having to adjust to institutional living proved impossible, and his brittle coping style was eventually overwhelmed, resulting in a crisis characterized by aggression and paranoid accusations. Putting together known history and current observations, Mr. L's clinical team diagnosed him with a paranoid and narcissistic personality disorder.

In this clinical vignette, several themes appear that characterize the course and prognosis of many personality disorders throughout life. First, dysfunctional behaviors do not arise de novo but have a history and have pervaded the individual's life in one form or another since young adulthood. In many cases, there may be long periods of increased stability in middle age that represent symptomatic remission, typically bolstered by stable relationships, successful occupational pursuits, and intensive therapeutic assistance. Not all personality disorders, however, will benefit from these stabilizing factors—particularly those with avoidant, schizoid, and schizotypal features. As seen in the illustrative case, major late-life stresses can exacerbate existing pathologic traits or lead to the reemergence of previous traits in ways that are different in kind but equally problematic as earlier in life. Lacking a longitudinal history and based strictly on observed behaviors, many personality-disordered individuals are typically diagnosed with major depression, bipolar disorder, or even late-onset schizophrenia, given the intensity of their symptoms. Although these diagnoses may present comorbidly, they are driven in part by the underlying personality disorder.

Cluster A Disorders

In late life, the diagnostic criteria for the three odd cluster disorders coalesce around a lack of desire for and openness toward interpersonal relationships. The tendency of the paranoid personality disorder to read malevolent intent into the actions of others leads to a lifetime of angry conflicts with others, while the aloof and strange demeanor of the schizoid and schizotypal individual precludes the formation of close relationships. As a result, odd cluster personality disorders tend to enter later life without the benefit of past interpersonal experiences that can, for less dysfunctional individuals, teach social skills and provide emotional support. It is believed that the pathologic cognitive and behavioral patterns of the odd cluster disorders tend to remain the same or even worsen with aging, with some conversion to schizophrenia spectrum disorders.

Paranoid, schizoid, and schizotypal individuals face age-associated stresses with variable responses. On the one hand, the lack of close relationships means that these individuals may feel a less emotional impact from the inevitable loss of family members or longstanding social contacts. However, when medical illness and disability occur, these same individuals often have great difficulty seeking help and coping with forced dependency on others, especially when placed in long-term care institutions. The result is often the increased expression of longstanding dysfunctional behaviors and defense mechanisms, including paranoid ideation, social isolation, and odd or idiosyncratic beliefs or rituals. There may also be an increased risk of psychosis to the extent that these disorders are considered potential precursors for late-onset schizophrenia.

Cluster B Disorders

Although lumped together under the “dramatic” cluster domain, these four personality disorders are heterogeneous in both expression and course over the life cycle. A central theme, however, is that while their psychopathology results in severe and, in some cases, deadly consequences, there is potential for symptomatic quiescence, improvement, or even remission in middle age when there are significant personal or occupational achievements or the presence of consistent interpersonal relationships. In addition, individuals with more personal, social, and/or financial resources and with less psychiatric comorbidity tend to fare better. By the same token, age-associated losses in relationships, social and occupational roles, physical attributes such as strength and beauty, and financial status can reverse many of these gains and prove devastating to the personality. For those individuals who had improved over their lifetimes, the stress of major losses can lead to the reemergence of previous dysfunctional cognitive and behavioral patterns, but in ways not always recognizable by the current diagnostic nomenclature. These relapses are inevitably complicated by comorbid psychiatric disorders such as major depression, neurocognitive disorders, anxiety disorders, and substance-related and addictive disorders.

There are several factors that limit the number of older individuals with antisocial personality disorder who are seen in clinical settings. First, their history of reckless and criminal behaviors and high rates of substance abuse often results in either death or incarceration long before they reach middle age. Second, these individuals have poor insight into their problems, few supportive relationships, and a lack of motivation to get help unless there is an acute issue that prevents their ongoing activities. As a result, both young and old antisocial individuals tend to avoid psychiatric settings.

Despite this rather grim assessment, clinical data reveal, somewhat surprisingly, that up to a third of antisocial individuals demonstrate significant clinical improvement if they survive into middle age, and about 12% to 33% no longer meet diagnostic criteria after 10 to 15 years. Individuals with poor social skills and higher degrees of aggression tend to do worse. The most salient changes include a shift away from aggressiveness, promiscuity, and criminal behaviors but replaced, in part, by substance abuse, depression, and somatization. All of these changes may reflect a general trend of decreased impulsivity and aggression with aging.

In long-term care settings, antisocial behaviors may include resistance to care, surreptitious substance abuse, abuse of other residents, and disregard for institutional rules regarding personal safety, hygiene, and schedules. Based strictly on observable behaviors, these older individuals might not meet the criteria for antisocial personality disorder, even though a longstanding lack of conscience—the hallmark of the disorder—is driving more age-appropriate dysfunctional behaviors.

In a similar fashion, individuals with borderline personality disorder demonstrate the potential for significant improvement and even remission in middle age, with one longitudinal study of 100 individuals finding that 75% no longer met the criteria after 15 years. This improvement was bolstered by personal and occupational successes and associated with increased physical attractiveness, higher intelligence, and self-discipline. Poorer outcomes were associated with a history of abuse, antisocial tendencies, high levels of aggression, and substance abuse. Even with improvement, however, there remained a significant risk for depression, substance abuse, and suicide.

Clinical case studies have described borderline individuals who demonstrate reemergent symptoms later in life but with a different appearance. Two key stressors are the loss of a spouse or partner and admission to a long-term care setting. Earlier defining symptoms of self-mutilation, impulsive and risky behaviors, and poor self-identity are attenuated and replaced by mood lability and depression, nonadherence to treatment, overuse of prescription medications, and alcohol abuse. In long-term care settings, however, the erratic and rageful interpersonal style seen in younger individuals with borderline personality disorder is often still present, creating havoc in the milieu.

Over their lifetimes, individuals with a narcissistic personality disorder often leave a wake of hurt and disgruntled personal and business relationships in their path, and though aware of their own anger or estrangement from others, they rarely attribute it to their own behaviors. Their sense of entitlement and demands on others may bring success in middle age, but with time they are particularly vulnerable to age-associated losses of personal attributes, gratifying occupational and social roles, and supportive if not somewhat subservient relationships. It becomes increasingly difficult for them to replace lost or jettisoned relationships over time, and they may find themselves in great need due to illness or disability but without adequate social support. The very process of aging proves to be a significant narcissistic injury, only worsened when they have1 to rely on the help of others they deem below them. In long-term care, the narcissistic personality disorder often presents as simultaneously depressed, rageful, and imperious toward staff, leading to frequent conflicts.

Histrionic personality disorder is probably the least studied in late life and has not been reported much in epidemiologic surveys or in clinical case studies. Like narcissistic individuals, however, histrionic individuals often lack deep, supportive social relationships and are equally buffeted by age-associated losses in physical appearance that allowed them to maintain some state of psychological equilibrium in the past. It has been suggested that somatization may be one dysfunctional avenue for older histrionic individuals to obtain attention and social gratification.

Cluster C Disorders

The anxious cluster disorders are thought to involve a lifetime of chronic personality dysfunction without significant remission, perhaps explaining why they tend to be some of the most commonly seen personality disorders in late life. Comorbid major depression is common and is often the presenting diagnosis when the underlying personality disorder is not appreciated. Avoidant and dependent individuals, in particular, often enter later life without having been able to cultivate many supportive relationships. As a result, the loss of a spouse or someone who served as their main support can be devastating and precipitate severe anxiety, depression, and incapacity. Given their poor social skills and inability to activate the social resources to meet their daily needs, these individuals may end up in dire circumstances, bereft of support, and at high risk in the community of abuse and neglect. The same psychopathology may be somewhat adaptive in long-term care settings, however, where forced dependency is a welcome respite for them and alleviates the difficult responsibility of having to assume self-care.

Individuals with obsessive-compulsive personality disorder tend to be less isolated in later life than avoidant or dependent individuals and have often cultivated sufficient social support due to their rigid insistence on routines and schedules. These individuals are more self-sufficient and may do relatively well with aging as long as they are able to find activities, part-time jobs, or other tasks to keep them busy and organized. Cognitive and physical disability can threaten this stability, however, especially when obsessive-compulsive personalities are unable to control their daily life according to preset rules and routines and have to depend on less reliable caregivers or long-term care staff. The latter circumstances can lead to significant conflicts with caregivers, as well as angry behavioral outbursts, anxiety and panic attacks, and depression.

TREATMENT

Given both the chronicity and pervasiveness of personality disorders, the initial goal of treatment is not to provide a cure but to reduce the frequency and intensity of symptoms. True symptomatic improvement is challenging and takes months, if not years, to accomplish, and will always be slowed down when comorbid medical and other psychiatric disorders are present. In turn, the presence of comorbid personality pathology, particularly Cluster B traits, has been shown to render cognitive behavioral therapy (CBT) less effective for late-life anxiety disorders. Similarly, treatments for major depression have been found to take longer and to be less effective in the presence of underlying personality disorders. Thus, realistic target symptoms should be established at the outset of treatment so as not to fall into the trap of building up excessive expectations that end up disappointing the patient and their social support as well as burning out the therapist.

There are several necessary treatment approaches for any older individual with a personality disorder. First, a general survey of active medical, neurologic, and medication-related factors that may be causing acute changes in personality expression must be ascertained to ensure that adequate treatment is being provided.

Many of these factors, including cerebral dysfunction, metabolic abnormalities, pain, and unmet physical or emotional needs, may be triggering and/or fueling interpersonal conflicts or disruptive behaviors that represent the personality disorder. Normal psychotherapeutic or pharmacologic strategies will fail unless these factors are addressed. This first step will necessitate significant involvement of multidisciplinary treatment team members, other treating physicians, and caregivers in order to implement the treatment plan as well as to serve as informants on response—particularly for individuals with cognitive impairment and/or physical disabilities.

Second, comorbid psychiatric disorders such as major depression, panic disorder, and substance-use disorders, among others, must be under treatment in order to reduce the psychological stress on the personality, as well as to clarify the personality disorder diagnosis. Diagnostic false positives are more likely during episodes of other psychiatric disorders, prompting many clinicians to defer personality disorder diagnoses during this time. A particular challenge at this juncture involves dealing with personality disorders within the setting of Alzheimer disease or other types of neurocognitive disorders, which can change personality itself or distort previously dysfunctional expressions of personality in ways both positive and negative. Some individuals may be more labile and impulsive, while others may be more apathetic and less likely to act out, especially when there is frontal or temporal lobe dysfunction. Unfortunately, it is difficult to predict the course of any given individual personality or personality disorder within the setting of major neurocognitive disorders, even when the specific regions of cerebral or subcortical damage are known. Although there are a number of existing acetylcholinesterase agents and one glutamate-receptor antagonist that can treat the cognitive, behavioral, and functional symptoms of Alzheimer disease and other major neurocognitive disorders, there is no evidence that any of these agents will have a discernible effect on personality disorders.

Third, clinicians must be willing and able themselves or have available to them a multidisciplinary team that can actively engage the older personality-disordered individual over time and through a variety of treatment modalities in order to foster a stable alliance. For older borderline, histrionic, narcissistic, dependent, and obsessive-compulsive subtypes, episodic clinical visits with an unpredictable schedule and therapy with too narrow a focus on medication management are liable to impair the therapeutic relationship. It is best to have several team members working together to provide an adequate density of time and attention in order to maintain stability and manage crises. On the flip side, older schizoid, schizotypal, paranoid, and avoidant subtypes might do best with shorter and more intermittent clinical visits, with a specific focus geared toward their stated needs. In all circumstances, there are inevitable medical and social issues—and often crises—that arise and require the involvement of a clinician who has made a firm commitment to the patient. Although such an approach seems obvious, it is all too often overlooked in a time-limited and overstretched mental health system.

Fourth, older individuals with personality disorders are often seen in long-term care settings, providing a structured setting in which to engineer environmental or behavioral plans. These plans require the input and creativity of mental health, social work, and nursing staff to be developed, implemented, and revised if necessary. The following clinical vignette illustrates how these plans may work.

Mr. P was a 78-year-old man with severe spinal stenosis who suffered from chronic back pain and was confined to a wheelchair. He had previously been diagnosed with both narcissistic and obsessive-compulsive personality disorders, as well as major depression. Shortly after being admitted to a nursing home, he frequently became enraged and verbally threatening toward nurses whom he accused of not adequately maintaining the battery on his electric wheelchair. On one occasion, he struck a nurse who was trying to reconnect a lead to the battery, accusing her of failing to follow his detailed instructions. A multidisciplinary clinical team met to discuss the situation and decided to condition Mr. P's access to the electric wheelchair on his cooperative behavior. A single staff member was assigned to work with Mr. P to maintain the battery, which limited the targets of his wrath. He earned hours in the electric wheelchair for each day that he went without cursing or abusing staff. As a result, the treatment team noticed a significant reduction in his abusive behaviors.

The key to success with any plan lies in the concerted and well-coordinated efforts of staff to implement its elements, monitor for improvement, and maintain communication. Pitfalls include disputes among staff members that often reflect the personality disorder's inner dynamics, lack of consistency, and lack of patience. When plans fail, staff members may inappropriately resort to punitive actions to deal with dysfunctional behaviors or attitudes, such as withholding attention or care, neglecting legitimate needs, using chemical restraints unnecessarily, or seeking alternative placement.

Psychotherapy

In older individuals with several subtypes of personality disorders and minimal to no cognitive impairment, both individual and group psychotherapeutic modalities may be helpful. Schizoid, schizotypal, paranoid, antisocial, and avoidant individuals tend to be more reluctant to engage in insight-oriented therapy and might do best through the indirect fostering of therapeutic relationships. In long-term care settings, this can be achieved through nonpsychiatric therapies (e.g., physical or occupational therapy) or activities (small jobs, arts and crafts, and music) that provide vital involvement, socialization, and meaning. Older individuals with borderline, narcissistic, histrionic, obsessive-compulsive, and dependent personality disorders will do better with direct forms of psychotherapy, especially CBT. Dialectical behavior therapy (DBT) is a particularly useful form of CBT that was originally developed for individuals with borderline personality disorder but has been adapted for individuals with major depression and personality disorders. DBT focuses on helping individuals become mindful of both the triggers and the consequences of their behaviors and then develop strategies to change them. Studies in younger individuals with DBT have found less overall depression and anxiety, fewer suicidal and self-injurious behaviors, and a decreased number and length of psychiatric hospitalizations.

Group psychotherapy can take on many forms for older adult individuals, ranging from psychoeducational forums to single-focus groups for socialization, bereavement, or caregiving to more formal therapy groups such as are found in a structured outpatient program. Group selection for the older personality-disordered individual will depend on their tolerance for a group setting, ability to participate without either monopolizing the group or acting out, and level of motivation. Cognitively intact individuals with reasonably good social skills are the best candidates.

Pharmacotherapy

Psychotropic medications can be used across several levels in the older patient with a personality disorder: (1) crisis management; (2) treatment of comorbid psychiatric disorders, such as major depression; (3) treatment of the personality disorder itself; and (4) treatment of the most salient target symptoms associated with the personality disorder. The first two levels are covered extensively in other parts of this text and are inevitably faced with every personality disorder. Treatment of the personality disorder itself is quite difficult given the heterogeneity of presentations, and the literature has almost exclusively focused on borderline, schizotypal, and antisocial subtypes. Even in the majority of those studies, the main focus of treatment was on selected target symptoms that were most problematic, such as impulsivity, aggression, and psychosis. All three of these common symptoms in both dramatic cluster and odd cluster personality disorders have been found to be partially responsive to antipsychotic agents, antidepressants, and mood stabilizers such as divalproex (Depakote) and carbamazepine (Tegretol). Many of the early studies looked at the use of tricyclic antidepressant agents and monoamine oxidase inhibitors to treat symptoms of personality disorders. Although they demonstrated some degree of efficacy, these latter agents are less practical in older adult patients due to their anticholinergic properties and propensity to cause orthostasis. In general, there is no evidence to date that clearly supports one particular agent or medication class as more efficacious than another for any particular symptom or personality disorder. As it stands, given the lack of data for older individuals, the selection of specific psychotropic medications for both young and old individuals with personality disorders will follow the same guidelines.

In older individuals, clinicians must hearken to the familial caveat to “start low, go slow, but go” when prescribing medications. However, another equally important caveat is to know when the use of medications might actually be counterproductive. It is risky to prescribe to patients with poor adherence to medications or hazardous use of them due to cognitive impairment, denial of illness, or impulsivity. In all of those cases, more structure is needed to administer the medications, either through a trusted family member or a visiting nurse or by transferring the patient to an assisted living or long-term care facility. Patients with obsessive-compulsive and dependent traits sometimes become fixated on medication doses and dosing schedules and spend excessive time discussing this with the prescribing doctor instead of dealing with more relevant issues.

Taking medication becomes a way for them to pathologically structure their relationship with the doctor, such as through increased dependency. In all of these situations, the clinician must weigh the potential benefits of the medication against the potential harm to the patient through misuse or the resultant exacerbation of dysfunctional behaviors.

55.3j Alcohol and Substance Abuse in Older Adults

Steve Koh, M.D., M.P.H., M.B.A., Hilary Gould, Ph.D., Omar Ghosn, M.D., and Michael Hann, M.D., M.B.A., M.S., C.P.E., F.A.C.H.E., F.A.P.A.

The most recent United States and global data projects rapid population growth of older adults. An increase in longevity contributes to this growth, even though countries with higher socioeconomic status have shown a decrease in fertility rates. In 2019, approximately 16.5% of the U.S. population was 65 years or older; projections based on U.S. Census data indicate that by the year 2050, this number is expected to reach 22%. This aging trend is not unique to the United States. The United Nations Department of Economic and Social Affairs projects that those above age 65 will account for about 16% of the total global population by 2050. Even within the older adult group, the proportion of the oldest old (above age 80) is increasing. Furthermore, the global ratio of males to females is narrowing due to improvements in male life expectancy. In 2013, this ratio in those above 60 was 76:100. By 2050, this will increase to 87:100. Within the United States, there is a clustering of older adults with disability, in poverty, or socially isolated in central urban centers or in remote areas. In this context, there is a likelihood of higher rates of substance dependence. Population trends also indicate that the aging cohort of adults who are currently considered middle age will reflect the substance use and misuse trends of younger cohorts.

As the U.S. population aged, classically held views on alcohol and substance misuse have evolved in the clinical setting. Alcohol and drug misuse continue to significantly contribute to worldwide disability and negative health outcomes. Older adults who started misusing in their younger years are now facing severe consequences from medical, psychiatric, and social perspectives. Once considered an "invisible epidemic" of substance misuse in the older population, clinicians are now faced with higher rates of co-occurring disorders that are complicated by the natural aging processes and cognitive decline. Most recent data from the Substance Abuse and Mental Health Services Administration (SAMHSA) indicates overall substance use of 165.4 million Americans 12 years and older, with alcohol use accounting for 50.8%. While alcohol use continues to be the highest contributor to substance use, nicotine use continues at 21.1%, and illicit drug use is on the rise at 13%. The National Household Survey on Drug Abuse from 2016 data suggested that by 2020, 2.7 million Americans aged 65 years or older will misuse prescription drugs, and 4.4 million older adults will require some form of substance abuse treatment. Despite the rise in substance use among older adults, forms of ageism continue to be common in clinical practice.

Several common barriers impede the identification of substance misuse in older adults, some of which are outlined in Table 55.3j–1. Many stereotypes of the typical older adults with substance abuse are prevalent in clinical care. For example, an older patient needing addiction treatment is often deemed to have been a life-long heavy drinker with failing health related to alcohol use and a limited to a nonexistent social network. The relatively healthy older adult who is drinking "moderately" is not considered to be in need of help and is often not assessed fully for the potential effect of alcohol on overall health and well-being. Also, substance use is addressed in a cross-sectional manner (i.e., if the patient is using now), and past chronic use history is often ignored. As the baby boom cohort enters the geriatric population, unique challenges face providers; along with the increased size of this cohort with changes in age distribution, there will be higher rates of excessive drinking, binge drinking, and illicit drug use.

Table 55.3j–1.
Barriers to Detection of Substance Misuse in the Geriatric Population

Barriers to the Clinician	Barriers to the Older Adult
Assumptions of lower prevalence of substance misuse in the geriatric population	Poor insight into substance misuse and reluctance to voluntarily seek help
Failure to screen appropriately for substance misuse in the older population	Lack of knowledge about the mental health system and treatment options
Masking of symptoms of substance misuse by other comorbid physical and mental/cognitive ailments	Feelings of shame, denial, desire to continue using, pessimism about treatment and recovery
Discomfort with addressing substance misuse with older adults	Cognitive problems—substance-induced amnesia, underlying neurocognitive disorder
Absence of collateral information from family members and caretakers	Family members and/or caretakers may not adequately report concerns of substance misuse
Assumption that older adults may not benefit from substance misuse treatment and prevention	Belief that other medical issues may be more important to address than substance misuse

Adapted from Crome I, Dar K, Janikiewicz S, Rao T, Tarbuck A. *Our Invisible Addicts: First Report of the Older Persons' Substance Misuse Working Group of the Royal College of Psychiatrists*. College Report CR 165, 2011.

An additional potential barrier to identification is the relative rarity of severe use disorders in older adults, where the prevalence of moderate to severe alcohol use disorder (AUD) is less than 4% and even lower in women, and illicit drug use disorders are currently less than 1%. On the other hand, 10% to 20% of older adults are drinking above recommended limits and are therefore at risk of having or developing problems even if they do not meet the criteria for a use disorder.

For older adults, a lack of understanding regarding the definition of at-risk use and who may benefit from treatment interferes with assessment or treatment-seeking behavior, which may be further compounded by denial. Similar to providers, patients may perceive physical symptoms (e.g., fatigue, sleep problems, anxiety, confusion) as normal or attribute them to a comorbid condition. Furthermore, age and substance-related declines in memory may result in underreporting of past and current substance use.

Mr. Doe is a 74-year-old man who was evaluated in the Emergency Department (ED) after a fall in which the patient sustained a hip fracture. In addition to hip pain, the patient endorses some ill-described upper abdominal discomfort. The patient's blood alcohol level (BAL) was 0.04 in the ED. The patient lives alone but takes care of himself and has a small social network of a few friends. He has a family, but they do not live nearby, and he is financially independent. When asked about general health habits, he reports that he does not smoke but drinks every day at dinner and before bed. The ED physician asked the CAGE questions, which upset the patient, who responded negatively to all items. The patient is taking hydrochlorothiazide and Lisinopril for hypertension and was recently prescribed Ambien as a sleep aid and a histamine antagonist for gastritis by his primary care physician (PCP). The ED physician documented that the patient's fall was likely secondary to the use of Ambien and declined to investigate the patient's drinking habits further due to the patient's irritation with the topic.

A review of the patient's medical record indicated that the patient received a mental health evaluation 6 months earlier at the request of his family. The family was worried about him living alone and wanted him to move into an assisted living facility. He was determined to be able to perform daily activities, although he was somewhat slow, and he rarely left home. There was no sign of dementia, but there was minor impairment in reaction time and problem-solving. When asked about alcohol use, he reported that he drank one drink at dinnertime and two drinks of sherry before bed. He described this pattern of drinking since he was widowed 15 years previous.

The case study illustrates several diagnostic dilemmas faced by clinicians who treat older drinkers:

- Mr. Doe did not seem to meet any dependence criteria.

- The patient, the ED physician, and the psychiatrist failed to make the connection that alcohol misuse was probably contributing to Mr. Doe's gastritis and to his presentation in the ED.

Mr. Doe was, however, drinking well above the recommended limits and was, therefore, an at-risk drinker, even if he did not present as the typical "alcoholic."

Take-home points:

- Diagnostic criteria and symptoms for alcohol and prescription drug misuse are not as applicable for older adults and may be confounded with comorbid medical illnesses.
- Lack of recognition by health care providers is often compounded by a lack of understanding of the benefits of reduced substance use when the patient is not physiologically dependent, or there is a general belief that there are few, if any, effective, accessible treatments to target substance misuse.
- Improved dissemination of current treatment methods and their efficacy, as well as continued development of other effective treatments, is essential.

HISTORY

Substance misuse among older adults as a distinct entity was first described in the research literature in 1964. In the 1960s and 1970s, researchers believed that substance misuse was rare in older adults and thus devoted little attention to this population as compared to younger adults. Health providers assumed that individuals with life-long addictions either died early or spontaneously improved in later life, and older adults with alcohol misuse were considered to likely have had a long history of drinking. Even the DSM-III-R, published in 1987, reads: "In males, symptoms of alcohol dependence or abuse rarely occur for the first time after age 45." Thus, until the past three decades, alcohol and drug misuse in older adults was rarely discussed in substance abuse or in the gerontologic literature. As the frequency of substance problems climbs in older adults, while it remains largely underdiagnosed and undertreated, attention to this issue has been increasing over time. Since 2013, there have been over 34,000 PubMed publications on the topic of older adults and substance use, with a peak number of publications in 2019. In routine primary care practice, however, screening and preventative measures for older populations are often still missing. More recently, studies have been conducted examining alcohol and prescription misuse in older adults and investigating treatment approaches better suited to this population. Recent studies indicate that while alcohol use continues to be the most common, prescription drug misuse has been on the rise and accounts for number two. Most importantly, prescription opioids and benzodiazepines are most concerning due to polypharmacy, sensitivity, and risks of harm, overdose, and death.

DSM-5 TERMINOLOGY

The Diagnostic and Statistical Manual of Mental Disorders, 5th edition (DSM-5) criteria for substance use disorder are considered identical for younger and older adults. Whereas distinctions were made between substance abuse and dependence in previous editions of the DSM, DSM-5 combines these diagnoses into a single disorder measured on a continuum from mild to severe. The essential feature of a substance-use disorder is a cluster of cognitive, behavioral, and physiologic symptoms indicating that the individual continues using the substance despite significant substance-related problems. Each of 10 separate classes of substances is addressed as a separate use disorder (e.g., AUD, stimulant use disorder) and is assessed clinically along a severity spectrum scale.

DSM-5 defines substance use disorder as a maladaptive pattern of substance use occurring within the previous 12 months leading to clinically significant impairment or distress. Diagnostic criteria include recurrent substance use resulting in failure to fulfill major roles or obligations, recurrent substance use in physically hazardous situations, and continued substance use despite persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance. Other criteria include the presence of tolerance and withdrawals, intense cravings, consumption of the substance in larger amounts or time periods than intended, persistent desire or unsuccessful attempts to cut down, and excessive time spent obtaining, using, or recovering from the substance. Finally, an individual with a substance use disorder may reduce or sacrifice important social, occupational, or recreational activities and continue to use the substance despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance. A patient's substance-use disorder is categorized as "moderate" if they meet two or three criteria and "severe" if they meet four or more criteria.

For the purposes of terminologic clarity and to reflect the transition to DSM-5 criteria, the term *abuse* will only be used generally in this chapter and will not be used to refer to the clinical entity described in previous versions of the DSM. However, *physiologic dependence*, which is defined as evidence of tolerance or withdrawal (Severity Spectrum Scale Items 4 and/or 5), continues to be clinically relevant and will be used in this chapter in accordance with the DSM-5 conceptualization of this term.

Although the diagnostic criteria for substance-use disorders are the same for younger and older adults, some of the criteria may be less relevant for the latter. For example, problems related to work or the family may not be relevant for a retired or widowed older adults. Older women tend to drink at home alone and thus would be unlikely to have legal or work-related difficulties. Similarly, an older adults with physiologic dependence on a benzodiazepine with chronic insomnia may have no other symptoms of a sedative, hypnotic, and anxiolytic use disorder and may be more prone to falls and cognitive impairment from the benzodiazepine use itself. On the other hand, health problems are often more prominent in the geriatric population and may be a motivating reason for changing alcohol and substance use.

ALCOHOL

Spectrum-of-Use Categories

As the DSM-5 criteria may be less ideally applied for older adults, alternate categories of substance use may be more appropriate, particularly for alcohol use. Individuals who drank less than one or two alcoholic drinks in the previous year are categorized as *abstainers*. Approximately 50% to 70% of older adults report abstinence, making this the most common late-life drinking pattern. The reasons for abstaining, however, may have implications regarding treatment and counseling about drinking. Although many individuals report life-long abstinence, other individuals stop drinking alcohol due to the onset or presence of an acute or chronic illness, while others abstain due to a previous history of alcohol problems. Identification of the latter group allows preventive monitoring and screening to help avoid future relapse and also alerts the clinician to increased vulnerability for mental health problems and cognitive declines. *Low-risk*, *social*, or *moderate drinkers* include individuals who drink within the recommended guidelines and are not using any contraindicated medications or having any problems related to use.

An *at-risk* or *excessive drinker* is defined as someone who does not meet AUD criteria but is drinking at a level that increases the likelihood of problems or negative consequences. Drinking above recommended limits would be included in this category (more than one drink per day and, in particular, more than three drinks in a day). *Problem drinking* is the term often used in place of abuse for older adults drinking at a level that is causing detrimental medical, psychological, or social effects.

Table 55.3j–2.
Common Signs and Symptoms of Potential Substance Misuse and Abuse in Older Adults

Anxiety
Blackouts, dizziness
Depression, mood swings
Disorientation
Family problems
Financial problems
Headaches
Incontinence
Increased tolerance to alcohol or medications
Legal difficulties
Memory loss
New difficulties in decision making
Poor hygiene
Falls, bruises, and burns
Idiopathic seizures
Sleep problems
Social isolation
Poor nutrition

Adapted from Barry KL, Blow FC, Oslin DW. Substance abuse in older adults: Review and recommendations for education and practice in medical settings. HRSA/AMERSA monograph; 2002, http://www.informaworld.com

The Spectrum-of-Use Categories and the DSM-5 Severity Spectrum Criteria are both based on knowledge from young and middle-aged adults, and the applicability and validity in older persons are questionable. Physiologic tolerance may occur in older adults without increased consumption over time due to the physiologic effects of aging. DSM-5 diagnostic criteria are also susceptible to self-report biases, including memory impairment, lack of insight, and unwillingness to acknowledge symptoms. Other signs and symptoms may alert the physician to potential alcohol and substance misuse in older adults (Table 55.3j–2). In addition, collateral information, particularly when cognitive impairment is present, from family, friends, employers, or others is an important source of information to supplement or confirm the patient's report.

Epidemiology

Several epidemiologic studies indicate that the prevalence of AUDs in the geriatric population is underestimated. This represents an unfortunate bias, as AUDs in older adults are shown to have a greater probability of responding to treatment than those developed at an earlier age. While drinking tends to decrease with age, recent studies have shown that aging cohorts' rate of drinking is rising. Furthermore, the aging baby-boom generation, with its higher rates of alcohol and substance use, is more likely than previous generations of older Americans to misuse alcohol. About 20% of adults aged 60 to 64 and around 11% over age 65 report current binge drinking (defined as five or more drinks on the same occasion in the past 30 days). It should be noted that these are definitions developed for the general population and are not those used for older adults. AUDs afflict 1% to 3% of the older adult population and significantly worsen their physical, psychiatric, and social condition. In addition, up to 30% of inpatient geriatric patients on medical floors and up to 50% of geriatric psychiatry admissions present with a concurrent AUD.

Gender-related changes in alcohol consumption are also quite relevant diagnostically in screening for alcohol misuse. Women have historically tended to curb their drinking as they age more than men; however, data analyzed from the past two decades suggest that the prevalence of drinking and binge drinking is increasing at a more rapid rate than it is for men. Older women are more susceptible than their male counterparts to the adverse effects of alcohol misuse, including medical morbidity, and are more apt to have comorbid medical conditions, depression, anxiety, and abuse of psychoactive medications. Furthermore, as men live longer, it will be important to continue the screening for alcohol misuse and consider preventative measures.

Rates of AUDs are greater in health care settings relative to community-based samples. Mental health clinics also have higher rates of AUDs compared to the community. Nevertheless, alcohol use and abuse in older people are often overlooked in the clinic. Ageism can unconsciously affect care givers, who normalize the patient’s complaints. Sleep problems can often be misperceived as always being a bad sleeper or a low appetite can be attributed to always being a picky eater. Older adults may also be wary of stigma and minimize their alcohol use, fearing being identified as “alcoholic.” On busy clinic days, symptoms that can be suggestive of an AUD, like poor energy and changes in mood, may be quickly explained and credited to a mood disorder or a medical condition. Furthermore, older women’s alcohol use can be overlooked secondary to stereotyping.

Etiology

The etiology of problem drinking in older adults has not been well studied. It is a common myth that older problem drinkers have a life-long history of alcohol-related problems. This myth is more accurate for illicit drugs and nicotine, whereas as many as one-third of older adults seeking treatment for alcohol misuse develop their problems in later life. Thus, although drinking patterns are often stable over time, increased drinking in later life is not unusual due perhaps in part to more free or unstructured time, a rise in disposable income, and losses of loved ones. Older adults also potentially face several stressful life transitions (e.g., retirement, menopause, the “empty nest” phenomenon, loss of friends), worsening medical conditions (e.g., chronic pain, multiple medical conditions leading to a reduction in mobility and decrease in functioning), and the adoption of new roles (e.g., widow[er], caretaker) as they approach an older age, thereby increasing the vulnerability to alcohol misuse. Treatment approaches for late-onset and life-long problem drinkers are currently the same; however, the distinction is important for clinicians as the former are more likely to go undiagnosed and, therefore, untreated.

Recommended Limits

Certain age-related factors, including physiologic factors that increase sensitivity to alcohol and drugs in older adults, have led the National Institute on Alcohol Abuse and Alcoholism (NIAAA) and the Center for Substance Abuse Treatment (CSAT) to set lower recommended limits for alcohol use for older adults. The maximum drinking limit for women and men over the age of 65 is no more than an average of one standard drink per day, or seven standard drinks per week which is 50% less than the recommended limit for younger men. Table 55.3j–3 provides a description of how to measure a standard drink. In addition, older adults should not consume more than three standard drinks in 1 day (i.e., binge drinking).

Aging leads to a decrease in lean body mass and total body water, an increase in blood–brain barrier permeability, and a heightened neuronal receptor sensitivity to alcohol. These physiologic changes increase the blood alcohol concentrations of older adults and lead to worse impairment compared to younger adults drinking the same amount. Another physiologic change that contributes to 20% to 50% higher alcohol blood levels in older adults is a reduction in the activity of gastric and liver aldehyde dehydrogenase. In addition, older adult individuals are subject to polypharmacy which puts pressure on the microsomal ethanol oxidizing system (MEOS) in the liver. The prescribed medications compete with alcohol to be metabolized, which ensures both alcohol and drugs accumulate in the bloodstream and lead to further toxicity.

Table 55.3j–3.
Alcohol Conversion Chart

"1 Standard Drink"

Beverage Type	Quantity
Beer	12 oz
Wine	5 oz
Fortified wine	3 oz
Hard liquor (80-proof distilled spirits)	1½ oz (i.e., "a shot")
Malt liquor	8 oz
Liqueur or aperitif	4 oz

Additional Conversions

Beverage Type/Quantity	# Standard Drinks
Beer:	
▶ 1 (6) pack of 16 oz cans/bottles	8
▶ 1 quart	3
▶ 1 liter (33.8 oz)	2.8
Wine (e.g., red, white, chianti):	
▶ 1 bottle (25 oz)	5
▶ 1 bottle (40 oz)	8
▶ Fifth	6
▶ 1 magnum	12
▶ ½ gallon	16
Fortified wine (e.g., sherry, port):	
▶ Pint	7
▶ Fifth	12
Hard liquor (e.g., rum, gin, tequila, vodka):	
▶ Fifth	18
▶ Pint	11
▶ Quart	20
▶ ½ gallon	40
▶ 1 bottle (25 oz)	17
▶ 1 bottle (40 oz)	27
Malt liquor (e.g., Old English):	
▶ 12 oz	1.5
▶ Forty (40 oz)	5

Screening

Utilizing brief, free, and validated instruments can be useful for screening for alcohol misuse to help in the prevention or early intervention of older adults at risk. If screening indicates misuse, further assessment and detail is needed to accurately diagnose a substance use disorder and develop an individualized treatment plan. Screening measures may be administered by verbal interview or by paper-and-pencil or computerized questionnaire with equal reliability and validity. Additional information may be helpful with screening, including attending to changes in behavior, mood, cognition, or appearance; unexplained symptoms; slurred speech; and lab results, including liver-function test abnormalities. If screening instruments are not sensitive to older age, it is generally recommended to reduce the threshold. Screening should also assess the quantity and frequency of alcohol use and is often more accurate when administered by an interviewer versus self-administration due to variation in individuals' definitions of a standard drink (see Table 55.3j–3 for a description of a standard drink).

Alcohol misuse may be a contributory factor to all of the geriatric common presenting problems in primary care: impaired intellectual function, immobility, instability, and incontinence. The PCP is in a prime position to implement those screening instruments to monitor the patient regularly, and even if the patient has stopped alcohol use, there may be the temptation to substitute with other substances such as prescribed medications.

In the PCP's office, a variety of presentations should raise suspicion and warrant screening for AUD:

- Worsening of an otherwise stable chronic medical condition (diabetes mellitus type II, gastritis, gout, hypercholesterolemia, hypertension, macrocytic anemia, osteoporosis, and Parkinson disease);
- A change in a stable medication regimen efficacy;
- Acute emergent medical problems like aspiration pneumonia, dehydration, fecal or urinary incontinence, gastrointestinal disorders, heart failure, hypothermia, malnutrition, orthostasis, syncope, and unexplained falls;

- Onset or worsening of psychiatric disorders anxiety, confusion, dementia, depression, insomnia, and Wernicke–Korsakoff syndrome.

The most appropriate screening assessments used in the geriatric population are the Short Michigan Alcoholism Screening Test–Geriatric version (SMAST-G) and the Alcohol Use Disorders Identification Test (AUDIT). The SMAST-G was developed specifically for screening older adults in a variety of settings, and its psychometric properties exceed those of other screens for the identification of AUDs in this population (Table 55.3j–4). The AUDIT and the abbreviated version, the AUDIT-C (Table 55.3j–5), assess the frequency of drinking and binging in the past year. The AUDIT-C score ranges from 0 to 12, with a higher score indicating an increased likelihood of alcohol use impacting health and safety. For older adults, a score of 2 or greater suggests the need for further assessment or recommendation of a brief alcohol intervention.

Table 55.3j–4.

Short Michigan Alcohol Screening Test—Geriatric Version (SMAST-G)

In the past year:	YES	NO
1. When talking with others, do you ever underestimate how much you actually drink?	(1)	(0)
2. After a few drinks, have you sometimes not eaten or been able to skip a meal because you didn’t feel hungry?	(1)	(0)
3. Does having a few drinks help decrease your shakiness or tremors?	(1)	(0)
4. Does alcohol sometimes make it hard for you to remember parts of the day or night?	(1)	(0)
In the past year:		
5. Do you usually take a drink to relax or calm your nerves?	(1)	(0)
6. Do you drink to take your mind off your problems?	(1)	(0)
7. Have you ever increased your drinking after experiencing a loss in your life?	(1)	(0)
8. Has a doctor or nurse ever said they were worried or concerned about your drinking?	(1)	(0)
9. Have you ever made rules to manage your drinking?	(1)	(0)
10. When you feel lonely, does having a drink help?	(1)	(0)
TOTAL SMAST-G SCORE (0–10)		

Two or more positive responses are indicative of an alcohol use problem.

Table 55.3j–5.
AUDIT-C Alcohol Screening

1. How often did you have a drink containing alcohol in the past year?

—	Never	(0 points)
—	Monthly or less	(1 point)
—	Two to four times a month	(2 points)
—	Two to three times per week	(3 points)
—	Four or more times a week	(4 points)

If you answered “never,” score questions 2 and 3 as zero.

2. How many drinks did you have on a typical day when you were drinking in the past year?

—	1 or 2	(0 points)
—	3 or 4	(1 point)
—	5 or 6	(2 points)
—	7 to 9	(3 points)
—	10 or more	(4 points)

3. How often did you have six or more drinks on one occasion in the past year?

—	Never	(0 points)
—	Less than monthly	(1 point)
—	Monthly	(2 points)
—	Weekly	(3 points)
—	Daily or almost daily	(4 points)

Possible range = 0–12. For older adults, a score of 3 or more is considered positive.

Other screening instruments that are commonly used in younger patients are not ideal for older adults for various reasons. The CAGE questionnaire is the most widely used alcohol-screening test. However, while the CAGE questionnaire has shown high specificity for detecting AUDs, there is a relatively low sensitivity for problem drinking. Poor insight into drinking is often a barrier for older adults' self-reporting of the amount of drinking, and for isolated older adults, there may not be enough social interaction to report if others are criticizing the drinking pattern. If a CAGE questionnaire is used, a modified version that only inquires about recent problems is most appropriate for older adults, and the threshold for indicating possible problems is one positive response.

The CAGE questionnaire and the SMAST-G can be used together to increase their sensitivity. Some laboratory markers of alcohol abuse can also be helpful in screening: liver enzymes like aspartate aminotransferase (AST) and γ-glutamyl transferase (GGT), mean corpuscular volume (MCV) of red blood cells, and specific alcohol biomarker carbohydrate-deficient transferrin (CDT). The sensitivity of MCV and GGT for alcohol use detection is higher in older adults compared to their younger counterparts. Laboratory values may indicate long-term abuse or recent use or misuse, including blood alcohol or blood acetate, a metabolite of alcohol. High blood levels of alcohol without signs of intoxication indicate high tolerance to alcohol.

Differential Diagnosis

Clinicians must be careful when diagnosing psychiatric conditions that occur only in the presence of intoxication or withdrawal, as both of these states may mimic psychiatric symptoms, including depressive, anxiety, and psychotic symptoms. Diagnosing based on historical self-report of symptoms leads to questionable reliability and validity, particularly with older patients and alcoholics who may have cognitive deficits as part of their illness.

Alcohol problems and depression are common comorbid conditions in late life. Depression symptoms can precede (primary or independent depression), occur simultaneously (indeterminate), or develop as a consequence (reactive or secondary depression) of significant alcohol use. Repeated use of depressants can induce mood disturbance and may affect the mood enough to meet the criteria for a major depressive episode. A diagnosis of primary depression may lead to a treatment plan targeting both disorders, whereas a secondary depression diagnosis would suggest treating the addiction and monitoring the depression. In the latter case, treatment with antidepressants is not likely to be effective, whereas termination of substance use can resolve mood disturbance. In one notable study of 42 patients who began detoxification with significant symptoms of depression, only 6% reported continued significant depressive symptoms at 4 weeks.

The high prevalence of chronic comorbid medical conditions in older adults may confuse the clinical picture and affect the ability of the physician to conclusively determine deteriorating functioning due to substance misuse. Alcohol problems contribute to cognitive deficits in later life. Wernicke–Korsakoff syndrome has a specific triad and is mostly caused by alcohol dependence. Alcohol-related dementia, however, can be difficult to delineate from Alzheimer disease due to overlapping symptoms and presentation. Dementia in older adult alcoholics is five times more prevalent than in abstinent older adults What’s more, around a quarter of patients who suffer from dementia have a comorbid AUD. In older adults, sedative intoxication can also be confused with progressive dementia. Withdrawal of the substance tends to stabilize cognitive and functional status for substance-related cognitive impairment but not for dementias.

Sleep disorders also frequently co-occur with excessive alcohol use. Alcohol use and aging are both associated with changes in sleep patterns. Alcohol has been shown to decrease sleep latency, decrease stage IV sleep, and precipitate or aggravate sleep apnea. Age-related changes can be exacerbated by alcohol use, depression, comorbid medical conditions, and medication use, including increased rapid eye movement (REM) episodes, decrease in REM length and stage III and IV sleep, and increased awakenings. On the other hand, abstinent alcoholics with poor sleep due to insomnia, frequent awakenings, and REM fragmentation demonstrate normalization of sleep periodicity and temporary suppression of REM sleep upon drinking, suggesting that alcohol may also be used to self-medicate sleep disturbances. Differential diagnosis, again, involves a historical account of the initiation of sleep problems and determining if symptoms subside with substance abstinence.

Course and Prognosis

Drinking patterns often are stable over time, but increased drinking in later life is not unusual due to factors idiosyncratic to an older population. In addition, aging patients can experience increased problems due to alcohol without increased consumption due to physiologic changes that increase sensitivity to alcohol and drugs, increased medication use, and the development of chronic health conditions.

Alcohol misuse is related to adverse effects in several physical health and psychiatric domains. Intoxication can lead to an increased risk of falls and motor vehicle accidents, especially in conjunction with medication interactions or other substance misuse. Chronic alcohol misuse is associated with multiple disease outcomes in several organ systems. More than 90% of older patients with a diagnosis of alcohol misuse have a history of depression and depressed older adults are three to four times more likely to have an AUD compared with nondepressed older adults. Like depression, late-life anxiety disorders can both be a consequence of problematic alcohol use as well as a primary psychiatric illness. Generalized anxiety disorder is the most common type of anxiety disorder in the older population, and those with the disorder are more than twice as likely to have a substance use disorder as those without an anxiety disorder.

Following depression, substance use disorders, particularly AUDs, are the second most common category of psychiatric disorders associated with completed suicide in the older population. Drinking among older adults elevates suicide risk through interactions with many factors that are more prevalent in this age group than in younger adults, factors such as depressive symptoms, medical illness, negatively perceived health status, and low socioeconomic support. Together, alcohol misuse and comorbid psychiatric illness are a potentially lethal combination. If appropriately addressed, however, positive outcomes and recovery can be expected. Studies have shown that more than 20% of treated older adult alcohol-dependent patients remain abstinent after 4 years.

Consequence of Moderate Use

Before discussing the negative prognoses for alcohol and substance abusers, it is important to acknowledge that moderate alcohol consumption may have positive effects on physical health and mental well-being. Low-risk alcohol consumption has been linked with a reduction in cardiovascular disease risk for men and women. For older adults without cardiovascular disease, moderate alcohol use has been associated with lipoprotein subclass distribution, including fewer small, low-density lipoprotein particles and increasingly large and medium-sized high-density lipoprotein particles. A cardiovascular protective effect of light to moderate alcohol consumption (1 drink/day for women or up to 2 drinks/day for men) has been reported in both the adult and older adult populations, but the findings are largely correlational. In addition, moderate alcohol use has been correlated with a lower incidence rate of type 2 diabetes mellitus in older adults and may reduce the risk of cognitive impairment and dementing illnesses.

Despite these potential health benefits, abstinence is recommended for individuals taking particular medications and those with a history of alcohol or drug abuse. In addition, although moderate drinking may protect against certain health problems, any alcohol consumption may be detrimental after a diagnosis of a chronic health condition (such as cardiovascular disease or diabetes). Furthermore, there is no evidence that initiation of drinking by nondrinkers will translate into reduced health risks, and moderate use may contribute to several negative health outcomes. Moderate alcohol consumption may reduce stroke risk due to blocked blood vessels but may increase stroke risk due to hemorrhaging or bleeding. The risk of breast cancer in women is increased by about 50% in women who drink three to nine drinks per week compared to fewer than three drinks per week. However, other sources show that even three to six alcoholic drinks per week are an independent risk factor for breast cancer in older women. In addition, there is a linear relationship between alcohol use and bone mineral density at the hip. Even limited alcohol consumption has been shown to impair one’s driving ability and may increase the chance of accidents and fatal injuries due to falls, motor vehicle accidents, and suicides. In addition, depression, memory problems, and other cognitive changes, liver disease, cardiovascular disease, and sleep problems have been associated with moderate alcohol use. Mental health providers also need to be cognizant that alcohol can negatively impact other mental health disorders. Even in the moderate use range, greater alcohol consumption adversely affects depression treatment. The converse is also true; the reduction of moderate alcohol use during depression treatment enhances treatment outcomes. Limited alcohol use may also negatively impact the course and prognosis of dementing illnesses and may precipitate or exacerbate the onset of personality changes and behavioral disturbances in patients with dementia. Depression, sleep problems, memory, and cognitive disturbances, and hepatic and cardiovascular diseases, have all been associated with moderate alcohol use.

Consequence of Severe Use

Severe AUD is associated with an increased probability of morbidity and mortality from disease-specific disorders, including acute pancreatitis, alcohol-induced cirrhosis, and alcohol-related cardiomyopathy. Older adults are also more susceptible than young persons to having worse hypertension in the setting of severe alcohol use. In addition, individuals having more than six standard drinks per day for a duration of more than 5 years are at an increased risk of heart failure secondary to nonischemic dilated heart disease and ventricular dysfunction. Alcohol also impacts the central nervous system (CNS) directly and indirectly. The prevalence of dementia is almost five times higher in severe AUD than in people with no AUD, and about 25% of the geriatric patients with dementia present with comorbid AUD. Alcohol directly modifies cell membrane fluidity, increasing the inhibitory activity of GABA receptors and inhibiting the excitatory activity of NMDA receptors. Alcohol also has indirect effects by causing thiamine, nicotinic acids, B vitamins, and folate deficiencies. Direct neuronal damage from alcohol leads to alcohol dementia, while indirect neuronal damage through thiamine deficiency causes Wernicke–Korsakoff syndrome and Marchiafava–Bignami disease.

Comorbidity of substance misuse with other medical and psychiatric conditions may impact the course, treatment, and prognosis of this condition. Substance misuse in earlier life can also impact later life, including increasing the likelihood of developing late-life mental health problems. Comorbid depression and alcohol misuse are not only common in later life but may have a reciprocal effect on each other. Depressed alcoholics are more likely than nondepressed alcoholics to have a complicated course of depression, manifested by increased suicide risk and social dysfunction. In addition, a history of alcohol abuse as a younger adult is predictive of a more severe and chronic depression course in later life. Almost 20% of people above the age of 65 who suffer from depression have a concomitant AUD. On the other hand, more than 90% of older subjects with AUDs also suffer from depression. Due to the complexity of the relationship, it is hard but important for a successful treatment plan to differentiate which disorder preceded or is driving the other. Moreover, dual diagnoses of internalizing disorders (depression and anxiety) and AUDs are the cause of more than 70% of completed suicides. They are also major contributing factors to household distress: domestic abuse and violence, separation and divorce, and socioeconomic drift. Depressed patients with AUD who successfully become abstinent use have progressively markedly improved psychiatric conditions compared with those who continue to drink. Vice versa, addressing anxiety and depression is also a critical target when treating AUDs.

Pharmacologic Treatment

Similar to the general population, AUD treatment for older adults consists of two phases, an acute detoxification strategy and a long-term prevention approach. The risk of complications, however, is higher for the older adult population. During alcohol withdrawal, older adults are at higher risk of both medical (e.g., cardiac arrhythmias and ischemias, fluctuating blood pressure, aspiration pneumonia) and neurologic complications (e.g., alcohol hallucinosis, delirium tremens, confusion, seizures, and Wernicke–Korsakoff syndrome) compared to the younger population, requiring closer medical monitoring. Wernicke–Korsakoff, characterized by peripheral neuropathy, ataxia, ocular paralysis, confusion, and confabulation, requires particular attention. Triggered by low serum levels of magnesium, Wernicke–Korsakoff is best treated with magnesium and thiamine supplementation for 5 days. Alcohol withdrawal is best managed with a benzodiazepine replacement and taper during the duration of the treatment. Scales like the Clinical Institute Withdrawal Assessment of Alcohol (CIWA) and Minnesota Detoxification Scale (MINDS) are used as a guide for health care providers to dose the benzodiazepine to avoid both excessive sedation from high doses or withdrawal complications from low doses. Short-acting benzodiazepines like lorazepam and oxazepam are recommended in older adults to avoid further risks of sedation. Nonbenzodiazepine options are less commonly used but remain useful in the management of agitation or in reducing the burden of high benzodiazepine requirements. Antipsychotics like haloperidol are often used in the case of severe agitation and hallucination. Beta-blockers such as atenolol and alpha-2 agonists like clonidine have been useful in managing agitation in the setting of tachycardia and hypertension. They, however, need to be judiciously dosed to avoid bradycardia and hypotension. Gabapentin and phenobarbital are most commonly used when a previous history of delirium tremens and intensive care unit hospitalization has been documented. Both medications enhance GABA-mediated activity, complementing the action of benzodiazepine to reduce excessive dosing in the acute phase.

After completing the detoxification phase, the challenge of remaining abstinent and preventing relapse arises. Evidence is suggestive that older adults have higher success remaining abstinent compared to their younger counterparts. More than 20% of treated alcohol-dependent patients remain abstinent 4 years later. What's more, older women seem to maintain abstinence better than men. Pharmacologic interventions are efficacious in reducing both the frequency and intensity of relapses, with modest effect sizes, however. Having a good safety profile, naltrexone is favored in relapse prevention strategies for older adults. Its antagonistic effect on the mu-opioid receptor is thought to decrease cravings and decrease the reward signals when drinking alcohol. Naltrexone's monthly injectable formulation may also come in handy to ensure compliance, especially when concerns of cognitive decline and forgetfulness are present. Acamprosate, an N-methyl-D-aspartic acid glutamate receptor inhibitor, is also a commonly used agent that has shown similar efficacy to naltrexone in preventing alcohol relapse and decreasing the severity of alcohol binges. Some studies have suggested synergistic effects and slightly improved outcomes when combining naltrexone and acamprosate. Pregabalin, topiramate, and baclofen are also commonly used for relapse prevention, albeit with less robust studies and evidence of efficacy.

TOBACCO

Epidemiology

Despite decreasing smoking trends, cigarette smoking kills more than 480,000 Americans every year and continues to be the leading cause of preventable disease and death in the United States. Approximately 70% of those deaths occur among those over the age of 60 years. Although often overlooked in older adults, smoking contributes significantly to poor health and disability in older adults. Smoking is the biggest risk factor for chronic obstructive pulmonary disease (COPD), which includes chronic bronchitis and emphysema. Smokers are 12 to 13 times more likely to die from COPD as compared to nonsmokers. Smoking contributes to frailty in older adults with chronic kidney disease and increases the risk of cardiometabolic, musculoskeletal, and cerebral complications. Among older adults, cigarette smoking also remains an important predictor of cancer mortality.

While smoking rates tend to decrease with age, one in five smokers is 50 years or older. Of community-dwelling individuals, 15.2% of adults aged 65 to 74 and 8.4% of those older than 75 are smokers. This rate is even higher in older African American men, where 22.1% of individuals 65 to 74 and 12% of 75 years old and older smoke. The importance of clinicians continuing to have a low threshold for smoking screening and working with patients toward smoking cessation does not change while taking care of older patients.

Etiology

Despite being wrong, impressions that late-life smoking cessation does not provide benefits and does not lead to overt changes in health outcomes may explain why older adults continue to smoke. In fact, it has been shown that compared with younger adults, a lower number of older adults express a desire to quit or make an attempt to quit smoking; however, they are more likely to succeed in their attempts. Adverse health events, including hospitalization or being diagnosed with a chronic illness, are associated with increased odds of smoking cessation among older adults.

Screening

Screening for tobacco should be included as part of the routine mental and physical health care for adults over the age of 60 and should be updated annually or whenever problems arise that may be related to tobacco use. There is no standard screening tool for tobacco in clinical settings, nor any adaptations for older adults. One method used for assessing the quantity and frequency of substance use (including alcohol, tobacco, and other substances) involves prospective recording and monitoring of use, retrospective accounts of daily use over a defined period of time (i.e., time-line follow-back method [TLFB]), or questions regarding average use. Although the prospective diary method is the gold standard, it is often impractical for screening assessments, as it requires more time and multiple visits. The TLFB method is the most commonly used technique in addiction studies, and 7-day TLFB assessments are highly correlated with the prospective method. Two difficulties arise with the TLFB. First, the week of measurement may not represent the typical week. Second, the TLFB method tends to underestimate use for less frequent users (compared to nonusers or frequent users). The TLFB also takes longer to administer than general questions and may vary due to variations in potency and modes of use.

Several tools currently exist that may be useful for screening tobacco use in older adults, including the Alcohol, Smoking, and Substance Involvement Screening Test (including ASSIST, ASSIST-LITE, and NIDA-Modified ASSIST) developed by the World Health Organization, the Tobacco, Alcohol, Prescription medication, and other Substance use (TAPS) Tool from NIAA, and the CAGE-AID which is adapted to include questions about other drugs besides alcohol. These measures screen for all categories of substance misuse. Compared to younger adults, older adults' reasons for quitting often include health risks to other family members, interactions with other medications, and changes in health status. Counseling on the health and longevity benefits of quitting is important to counteract commonly held misbeliefs that "the damage is done."

Course and Prognosis

Quitting smoking at a later age does not automatically cleanse the body from chronic smoke and toxin exposure and insults to the body. It can, however, reduce the risk of developing or dying from cancer or other medical conditions. Even quitting smoking at the age of 80 or older reduces the risk of developing or dying from cancer or other diseases. Among those diagnosed with cancer, smoking cessation improves treatment prognosis. On the other hand, continued smoking after a cancer diagnosis worsens the prognosis. It can lead to poorer response to treatment, increased chance of recurrence, increased chemotherapy side effects and toxicity, and increased chances of consequent primary tumors.

Impressions that late-life smoking cessation does not provide benefits and does not lead to changes in health outcomes are patently false. Even in older age, smoking cessation can decrease overall morbidity and improve quality of life. Older adults who quit smoking also experience many other health benefits, such as a lower risk of cognitive decline, a lower risk of polypharmacy, improved overall health outcomes, and improved quality of life. Despite the proven benefits, only 1 in 20 older adults attempting to quit smoking succeed. Smoking and nicotine addiction are chronic, relapsing conditions. Successful smoking cessation often happens following numerous interventions and attempts to quit. Treatment plans can be more successful when they include educating older adults about the benefits of quitting smoking. Older adults should also be encouraged to use evidence-based pharmacologic treatments, especially if they have failed to quit smoking on their own multiple times in the past.

Pharmacologic Treatment

Nicotine replacement therapy (NRT) is based on substituting the nicotine ingested by smoking with various forms of nicotine delivery methods with the goal of minimizing withdrawal symptoms when attempting to quit. NRT is currently the most studied pharmacologic treatment in older adults, and the limited available evidence suggests NRT is efficacious for smoking cessation among this population. NRT is available in different forms: patch, gum, inhaler, sublingual tablet, lozenge, and spray. All forms of NRT improve the chances of success by 50% to 70%, with no difference in effectiveness between the various forms.

The Food and Drug Administration (FDA) has also approved two non-nicotine–containing medications for smoking cessation: bupropion and varenicline. Varenicline facilitates smoking cessation through its partial agonist properties at the α4 β2 nicotinic acetylcholine receptor that both minimizes nicotine withdrawal symptoms and reduces the rewarding properties of nicotine. It is well tolerated in older adults and does not require dose adjustment based on age alone. Varenicline, however, should be used with caution in the presence of psychiatric disorders as it may worsen depression and increase the risk of suicidal thinking and behavior. Bupropion's effects on smoking cessation are thought to be independent of its antidepressant properties; its mechanism of action to decrease cravings has been attributed to the inhibition of the reuptake of dopamine in the CNS. Bupropion should be used with a reduced dose in older adults and should not be used in the case of comorbid epilepsy. Combining medications has synergistic effects and increases the chances of success but requires a cautious approach with the older adult to avoid the risks of polypharmacy.

Adverse health events, such as hospitalization or being diagnosed with a chronic illness, are associated with increased odds of smoking cessation among older adults. Among older adults attempting to quit smoking or who recently succeeded in quitting, more than a third (37%) used counseling and/or FDA-approved cessation medication to quit; 9% used at least one type of counseling from telephone quitlines, one-on-one counseling, cessation clinic, class, or support group. Very few used counseling without medication or used a specific type of counseling to have a reliable estimate. Thirty-four percent used at least one type of FDA-approved cessation medication, with the largest proportion, 29%, using NRT. Ten percent used varenicline, and too few used bupropion to be reliably estimated. Only 6% used both counseling and FDA-approved cessation medication. Cessation counseling, including individual, group, and telephone counseling, and FDA-approved cessation medications were found to be effective methods individually.

However, counseling and medications were found to be more effective when combined.

Because nicotine addiction is a chronic, relapsing condition, successful smoking cessation often requires repeated intervention and multiple attempts to quit. In particular, older adults may benefit from being informed by health care providers that they can still derive substantial health and quality-of-life benefits from quitting and that, even though they may have tried to quit unsuccessfully many times, they can still succeed in quitting, and that their chances of doing so are better if they use evidence-based tobacco cessation treatments.

TETRAHYDROCANNABINOL

Since 1970, marijuana has been classified as a Schedule I substance under the Controlled Substances Act (CSA). However, the United States is in the midst of a cultural shift regarding its perception of and the potential medicinal applications considered appropriate for marijuana. As of 2021, the medicinal use of marijuana is legal in 36 states, the District of Columbia, and four U.S. territories. Additionally, eight states, the District of Columbia, and two U.S. territories have passed legislation to regulate marijuana for nonmedicinal use. The wave of legalization is occurring in conjunction with a societal shift in the perception of marijuana. In the United States, there has been a general decline in stigma associated with marijuana use as well as a decline in the perceived risk of marijuana use, although these perceptions vary by state and region. The increasingly legal use of and easing access to marijuana, as well as a decrease in stigma associated with its use, is also affecting the substance use patterns of older adults.

Epidemiology

Marijuana is the most commonly used illicit substance among older adults, and older adults currently represent the fastest-growing demographic of marijuana users. According to a secondary analysis of data from the National Survey on Drug Use and Health, the prevalence of past-year marijuana use by older adults is estimated to have increased from 2.4% in 2015 to 4.2% in 2018. The rate of increase in marijuana use among older adults was particularly significant for women, racial/ethnic minorities, those with higher family incomes, and those with mental health problems. Multiple factors contribute to the rise in marijuana use by older adults, including a decrease in stigma and an increased interest in the possible benefits of marijuana for chronic health conditions. Additionally, the risk associated with the co-use of alcohol and marijuana in the older adult population was observed to be higher than the risk of using either independently.

Etiology

Older adults are increasingly using marijuana for medicinal purposes to treat conditions such as pain, insomnia, neuropathy, and anxiety. Although medicinal marijuana is typically well-tolerated in older adults, aging-related factors may pose specific risks. With advancing age, lean body mass and total water volume decrease relative to total fat volume, thereby decreasing total body volume and subsequently increasing the serum concentration, absorption, and distribution of alcohol and drugs in the body. Furthermore, reduction in liver mass and decreased hepatic blood flow results in slower drug metabolism, and changes in renal function can lead to the build-up of some substances. At the same time, the response to the CNS-active drugs is frequently exaggerated due to age-related decline in CNS function and increased pharmacodynamic sensitivity for some psychoactive drugs, thus amplifying the response to sedative-hypnotic and mind-altering drugs. The presence of dementia also increases the likelihood of intoxication and impaired functioning. Paradoxically, however, recent research suggests the possibility that cognitive functioning may actually improve when patients use medical marijuana due to factors such as improved sleep and pain control. However, age-related changes in drug sensitivity vary by drug, and pharmacodynamic changes associated with aging continue to be an area of investigation.

Screening

As marijuana increases in popularity, potency, and medicinal purposes, it is imperative to screen older patients for current use. When screening for substance misuse, using nonstigmatizing language and an empathic nonconfrontational style can be especially important for older adults. The White House Office of National Drug Control Policy released guidance around terminology in 2016, such as replacing labels like “addict” or “abuser” with the terminology of “substance use disorder,” “unhealthy use,” or “harmful use.” Cannabis use can be particularly challenging to obtain standardized measurements due to variations in the potency of strains, forms (e.g., flowers, oil, waxes), and modes of use (e.g., smoking, vaporizing, ingesting, topical). Similar to screening for alcohol misuse, many cannabis screeners target functioning and sequelae of use and do not take into consideration developmental changes in older adults. For example, the Marijuana Problem Scale measures negative consequences related to motivation and productivity, work and finances, physical health, and memory impairment which are easily confounded with the aging process. Most screening measures for problems related to marijuana use target adolescents and young adults. The Cannabis Use Disorder Identification Test-Revised (CUDIT-R) developed from the AUDIT is often recommended for use in older adults, although it has not been studied extensively. The CUDIT-R is a 20-item self-report measure of cannabis misuse in the past 6 months.

Risks

Older adults frequently suffer from chronic comorbid health conditions and are more likely to be taking multiple medications than the younger population. Polypharmacy and medication interactions in the context of marijuana use increase the possibility of medical complications in older adults using marijuana. Marijuana is chemically complex, but the two primary active ingredients are Tetrahydrocannabinol (THC) and Cannabidiol (CBD), both of which may alter hepatic metabolism and could alter blood levels of other medications. Older patients taking antiepileptic or blood thinners should be particularly cautious when considering marijuana use, as various studies have shown that blood levels of these medications may be altered when using marijuana. Marijuana use has also been shown to increase heart rate and blood pressure, although there is minimal evidence suggesting a link between marijuana use and an increased risk for cardiovascular events. Nonetheless, it is recommended to screen patients who use marijuana for cardiovascular disease.

Withdrawal

Although there is emerging research studying cannabis withdrawal, there is a paucity of research on cannabis withdrawal in older adults specifically.

Cannabis withdrawal syndrome (CWS), as defined in the DSM-5, occurs after the cessation of prolonged or heavy cannabis use. CWS symptoms include:

1. Irritability, anger, or aggression
2. Nervousness or anxiety
3. Sleep disturbance
4. Appetite or weight disturbance
5. Restlessness
6. Depressed mood
7. Somatic symptoms, such as headaches, sweating, nausea, vomiting, or abdominal pain

A recent meta-analysis suggests that up to 47% of patients who regularly use marijuana or demonstrate physiologic dependency experience CWS after discontinuing marijuana consumption. Cannabis withdrawal has also been associated with insomnia in one-third of patients after discontinuing cannabis. Cannabis withdrawal has been associated with lower total sleep time, worse sleep efficiency, longer sleep latency, shorter REM latency, lower slow wave sleep, and periodic limb movement. However, further research is required to study this phenomenon, more specifically in the older adult population.

Pharmacologic Treatment

Various studies have been conducted to evaluate the efficacy and safety of medical cannabinoids in a variety of conditions in adult patients, and in a substantial number of studies, older subjects were included. However, there is a general lack of evidence concerning the use of cannabinoids, specifically in older patients, resulting in a scarcity of data to guide treatment decisions. A review of studies performed that included older patients in the study population indicated no efficacy of medical marijuana on dyskinesia, breathlessness (versus placebo), chemotherapy-induced nausea and vomiting (versus prochlorperazine), or oral THC in the symptomatic treatment of behavioral problems in dementia. However, sample size and methodologic quality may have biased these conclusions. Further research on cannabinoids, specifically in the older population, is needed.

BENZODIAZEPINES

Epidemiology

Benzodiazepines are one of the most common classes of prescription medications in the United States. Benzodiazepine use increases with age and tends to be chronic in late life, which may increase the risks for fractures, subtle cognitive decline, and benzodiazepine dependence. According to the CSAT, 23% of all prescriptions written for older adults are for benzodiazepines. Despite the wide use of benzodiazepines, the American Geriatrics Society Beers Criteria recommends benzodiazepine use be limited in the older population to seizure disorders, REM sleep disorders, benzodiazepine withdrawal, alcohol withdrawal, severe generalized anxiety disorder, periprocedural anesthesia, and end-of-life care. Commonly, sleep disorder is the indication cited for benzodiazepine use in the older adult population, accounting for approximately 59% of total prescriptions; this is despite the fact that long-term benzodiazepine use does not help with sleep restoration. Sleep disorders occurring later in life are thought to be related to decreased activity of the suprachiasmatic nucleus, contributing to a disruption of circadian rhythms in older adults, including the nocturnal secretion of endogenous melatonin. However, the iatrogenic contribution of medications, including stimulants, antihypertensives, decongestants, chemotherapy, and respiratory medications, cannot be overlooked.

Etiology

While it is well established that benzodiazepines increase the risk of cognitive impairment, delirium, fall injuries, fractures, and motor vehicle accidents in older adults, there remains insufficient research on the impact of these medications on the older population. Studies on this topic are made more difficult for a variety of reasons, including a low overall 12-month prevalence of sedative, hypnotic, or anxiolytic use disorder diagnoses in older adults and less frequent referral to mental health resources than younger patients. This occurs despite the high rate of benzodiazepine prescriptions and commonly occurring clinical “red flags” of physiologic benzodiazepine dependence, including:

- Long-term use
- Rebound anxiety and insomnia on withdrawal from the drug
- Strong desire to use benzodiazepines
- Driving while under the influence of benzodiazepines
- Use of benzodiazepines despite falls
- Use of benzodiazepines in addition to other hypnotics
- Continuing use of benzodiazepines despite physicians’ recommendations to discontinue

Screening

In 2020, the U.S. Preventive Services Task Force revised previous guidelines and now recommends screening all adults for unhealthy drug use when appropriate treatment services can be offered. Benzodiazepines that were previously clinically appropriate for patients may become problematically related to changes in health status or aging. All prescribed medications should be reassessed as patients approach the age of 65, and prescription drug misuse should not be overlooked. As with all substances, attention to functioning and impairment is paramount, and problems can develop gradually and subtly. Specific to benzodiazepine use, assessing cognitive and memory-related impairments, diminished psychomotor abilities, deleterious events such as automobile accidents, falls, behavioral disinhibition, and worsening psychiatric symptoms are relevant. When problematic substance use or risk of misusing substances is suspected, it may be appropriate to provide routine toxicology screening (urine, saliva) to determine if additional assessment is necessary or to monitor progress. It is important to note, however, that urine drug screening does not detect all benzodiazepine use. Furthermore, there is consensus that routine use of laboratory tests as screening tools in the primary care setting is not recommended.

Differential Diagnosis

The DSM-5 diagnostic criteria for substance use disorders, including sedative, hypnotic, and anxiolytic use disorders, are the same for both young and older adults. However, differences in life circumstances may make the detection of a sedative use disorder more challenging for older adults. Older adults with physiologic dependence on a benzodiazepine with chronic insomnia may have no other symptoms of a sedative, hypnotic, and anxiolytic use disorder and may be more prone to falls and cognitive impairment from the benzodiazepine use itself. Age-based biases are also commonplace among physicians and caregivers and contribute significantly to the misdiagnosis of comorbid conditions and the misuse of benzodiazepines. Physicians and family members often overlook clinical signs of sleep disorders in older adults, including somnolence and fatigue, as signs of normal aging. Common sleep disorders, including sleep-disordered breathing and periodic limb movement syndromes, have been shown to benefit from nonbenzodiazepine evidence-based treatments. Overnight recording of the apnea–hypopnea index is indicated in patients with symptoms of sleep disorder breathing, including high snoring severity, unintentional napping, and/or excessive daytime sleepiness. Primary insomnia in older adults may be initially treated using numerous nonpharmaceutical tools to improve sleep hygiene, such as limiting naps, adjusting medications, avoiding stimulants like coffee, environmental improvements, examining sleep problems, and other specific treatments. Nonbenzodiazepines sedatives like zolpidem are often considered to be safe and effective in older adults, but recent research shows that they may lead to as many fractures, falls, and delirium as benzodiazepines.

Course and Prognosis

Despite clear indications that benzodiazepines are not the preferred agent for long-term treatment of anxiety, this is the second most common reason for the prescription of a benzodiazepine to an older adult, often in the absence of first-line antidepressant medications. Risk factors for anxiety disorder in older adults include female gender, low socioeconomic status, family history, external locus of control, the current level of perceived stress, poor primary support, and poor social support. While SSRI and SNRI medications are associated with falls and an increased risk of hyponatremia in older adults, their adverse effect profile is favorable in the chronic treatment of anxiety compared to benzodiazepines. Evidence for the nonpharmacologic treatment of anxiety in the older adult population is conflicting regarding cognitive behavioral therapy, physical therapy, and other behavioral approaches.

Withdrawal and Treatment

Abrupt or excessively rapid discontinuation of benzodiazepines can lead to benzodiazepine withdrawal, particularly if use has been long-term. Benzodiazepine withdrawal poses clinical risks, including rebound anxiety and seizures. Conversely, safely tapering benzodiazepines in the older adult population may have several benefits, including a decreased risk of falls. However, despite multiple guidelines and consensus statements advising against the use of benzodiazepines for older adults, prescription rates remain high. Effective clinical strategies for tapering long-term benzodiazepine use include combining clinical education and medication review as well as consultation focused on a clinical reassessment of benzodiazepine benefits and harms. Various tapering protocols have been studied, ranging from 4 to 22 weeks in duration; however, there is a general lack of research in older patients regarding the ideal rate for tapering benzodiazepines.

OPIOID ANALGESICS

Epidemiology

In the United States, the prevalence of substance use disorders in older exceeds 5.7 million people, with opioid use disorders increasing at an alarming rate. Data from multiple agencies, including the Centers for Disease Control (CDC), have documented an alarming rise in prescription opioid analgesic abuse with a concordant rise in attributed mortality. The opiate's impact on the older population is second only to alcohol, accounting for up to 22% of substance-related inpatient admissions. While a large percentage of the older population suffers from some form of chronic pain, often resulting in pain management with opioid analgesics, there is currently no evidence for the long-term effectiveness of opioid analgesics in the treatment of persistent noncancerous pain conditions in older patients. Despite growing concerns for opioid analgesic misuse, it is important to note that pain continues to be undertreated in adults.

Etiology

Declining physical health and physiologic changes associated with aging affect the metabolism of medications and, thus, the potential for medication misuse. Previous and comorbid psychiatric diagnoses, poor health status, social isolation, and female gender also increase the risk for prescription drug misuse. Many cases of psychoactive medication misuse have been shown to be unintentional on the part of the patient or physician. The drugs are usually obtained with an appropriate prescription for a specific health-related purpose, either a physical condition or emotional distress. An older patient may misunderstand the directions, their confusion may be compounded by multiple medications, or misuse may occur due to a prescription that is not appropriate for an older adult. Unintentional misuse can progress into abuse to obtain the desirable effects. Physiologic dependence on psychoactive medications without meeting additional DSM-5 substance use disorder criteria can also result from even therapeutic dosages for brief periods. Aging also involves increased sensitivity to over-the-counter and prescription medications, with women demonstrating even greater sensitivity.

Screening

Given the high utilization of medical services by older adults and because a large percentage do not self-identify as substance misusers, physicians and health care staff can be critical for identifying individuals with alcohol and drug problems. Screening can be verbal, written, computerized, and by general query or semistructured questions. Involvement of collateral or caretakers may be clinically appropriate. Assessing for dysfunction in age-appropriate domains and functioning, such as interference in social activities rather than problems with work, should be utilized. Screening measures previously mentioned, such as the ASSIST, TAPS, and CAGE-AID may provide clinical utility, although research studies in older adults are limited. Screeners specific to opioid misuse, opioid use disorder, and calculating benefit–harm ratios in older adults have not been well-studied or replicated. Some research suggests that the Opioid Risk Tool (ORT) has clinical validity in older adults and measures demographic variables and family and personal history to alert providers who may be at the most risk. If screening indicates misuse or concern for risk, further assessment is needed for diagnosis and treatment.

Withdrawal and Pharmacologic Treatment

Factors such as opioid withdrawal, opioid-induced hyperalgesia, and chronic noncancer pain make treatment of opioid use disorders challenging for older adults. Medication-assisted treatment (MAT) involves the use of U.S. FDA-approved medications in combination with counseling and behavioral therapies to treat opioid use disorders. Although MAT has been shown to be effective in the treatment of opioid use disorders for older adults, its utilization only ranges from 7.9% to 9.8%. This underutilization may stem from a failure to clinically recognize opioid use disorders in older adults, given the differences in life-factors compared to a younger population. The Canadian Coalition of Seniors' Mental Health's guidelines for the treatment of opioid use disorder in older adults recommends the use of buprenorphine as a first-line medication for both withdrawal management and maintenance therapy, with second-line agents including methadone, slow-release oral morphine, and naltrexone. Studies have examined the use of methadone in older adults for the treatment of chronic opioid misuse and physiologic dependence and found that they were no different from their younger counterparts in terms of medical and psychiatric problems or employment but did significantly better in treatment. Despite this more positive prognosis, older adults are thought to be more susceptible to the stigma of drug addiction, old age, psychotropic medication use, depression, poverty, race, and HIV status associated with methadone treatment.

The American Geriatric Society recommends that acetaminophen be used as a first-line agent in the treatment of pain in the older adult population. An appropriate second line for pain management includes SNRIs, gabapentin, and pregabalin alone or in combination with acetaminophen. NSAIDs should be used sparingly as older adults are considered more susceptible to the potential gastrointestinal adverse effects of these agents. Tricyclics have been shown to be somewhat efficacious in the treatment of pain in the general population; however, their use in the older population is not recommended, given their significant adverse effect profile.

ILLICIT DRUGS

Epidemiologic data for illicit drug use, such as amphetamines, heroin, hallucinogens, and cocaine, in older adults are limited. Data from the early 1990s in the Epidemiologic Catchment Area Study estimated lifetime prevalence rates for substance misuse to be 0.12% for older men and 0.06% for older women and a lifetime history of illicit drug use to be 2.88% and 0.66%, respectively. More recent work, however, suggests that illicit substance abuse is increasingly common in adults seeking treatment. Most recent studies indicate a gradual increase in the prevalence of illicit drugs in the older population. Studies looking at perspectives of illicit drugs show an overall decrease in negative opinions about commonly misused substances like marijuana and stimulants. It is important to note that the overall rise in prevalence in this age group is relatively unique when compared to other age groups. This trend likely reflects the aging of the baby boom cohort and is predictive of further increases in illicit substance use and abuse in older adults in the next decades.

The data on illicit stimulants (either amphetamine or cocaine use) in older adults is not very consistent. Some report an overall rise in misuse in the last decade, with prevalence rates between 2% and 3% of all substances. Data indicate higher rate increases of cocaine and methamphetamine use in underrepresented communities in recent years. What is unclear is if these higher reports indicate actual new incidences of use, results from higher screening from clinicians, or natural aging of the younger population with past, ongoing use. Additionally, it is not clear if the prescription stimulants are being cited as misuse by those surveyed. For example, over the past decade, there has been a significant increase in attention-deficit/hyperactivity disorder diagnoses in middle to older age adults. This has led to an increase in prescription stimulant use. The risk of stimulants in older adults is not trivial. Cardiovascular accidents in the form of myocardial infarctions and strokes are commonly reported by clinicians. Hallucinogen usage rate and prevalence in older adults are even more difficult to review. Either because of a decrease in access to these substances as one ages or a decrease in interest in these compounds in older age, most studies indicate less than 1% of misused substances being hallucinogens. However, there does seem to be increasing interest in treatments with ketamine and LSD usage in clinical settings with the older population. It is unclear how this may translate to misuse in the years to come.

In the aging population, while the data are largely unclear on specific illicit drug use, what is certain is that the misuse rate has been increasing. How these substances will interact and impact the overall health of older adults in the context of age-related biopsychosocial changes is of critical importance for the clinician to understand. It is unclear how stimulants and hallucinogens will impact age-associated cognitive decline or cardiovascular changes. It is unclear how different new onset of use will compare to long-term use. The important factor is that there is enough evidence to encourage clinicians to screen for illicit drug use early and continue to monitor even into older age. Illicit drug use can often be determined by a simple urine test. The majority of drugs are detectable in a urine drug screen for 4 days or greater, with some detectable after several weeks. Other physical signs of intoxication for different substances can be determined by physical examination. Intoxication with sedative, hypnotic, or anxiolytic substances or opioid medications results in decreased blood pressure, respiratory rate, pulse, and body temperature, while amphetamine or cocaine intoxication generally induces the reverse.

NONPHARMACOLOGIC THERAPIES

Older adults with substance misuse are underrepresented in research, policy initiatives, and clinical settings. Many research studies exclude patients over the age of 65, resulting in a significant gap of knowledge regarding the neurobiology, treatment response, and prognosis of addiction in later life. On the clinical side, older adults are less likely to be screened for substance use disorders, and clinicians may misattribute declines in functioning and quality of life to age or comorbid medical conditions. Compounding this, older adults are the least likely to perceive treatment needs and use treatment services. Even once identified for treatment, many face ageism when seeking services; for instance, substance use treatment centers often discriminate against older adults, not allowing them to enter into treatment programs. Only one in five treatment centers offers services specifically designed for older adults.

Despite the paucity of research and limited clinical services, evidence suggests that older adults are capable of change and benefit from treatment. This is particularly true when interventions are adapted to age-related physical, cognitive, and psychosocial needs. Studies have suggested that older adults are more likely to complete treatment, have improved outcomes relative to middle-aged adults, and can benefit from varied intervention approaches. In addition to pharmacologic therapies discussed in each subsection above, the following section includes information on brief interventions, psychosocial interventions, 12-step recovery programs, moderators and correlates of treatment response, and partial-hospitalization (PHPs) and intensive outpatient programs (IOPs).

Brief Interventions

Low-intensity, brief interventions or brief therapies are cost-effective, practical techniques that may be useful as an initial or adjunctive treatment approach with at-risk and problem users across a range of clinical settings. Brief interventions are time-limited and nonconfrontational and range from unstructured counseling and feedback to more formal therapy. As the interventions were developed using concepts and techniques from the behavioral self-control literature, one trademark of brief interventions is to encourage individuals to change their behavior through motivational interviewing. As older adults with substance misuse often experience shame about their substance problem, nonconfrontational and supportive approaches are well suited, and labels (e.g., addict, alcoholic) are best avoided.

Six elements under the acronym FRAMES have been identified by the SAMHSA Consensus Panel as critical to brief interventions:

- Feedback about personal risk
- Responsibility for change
- Advice from the clinician
- Menu of treatment options
- Empathic style
- Self-efficacy or optimistic empowerment

Brief interventions or therapies may be provided individually, with family, or in group settings.

Randomized clinical trials of brief interventions for alcohol problems among older populations have demonstrated the efficacy of the treatment, that is, reduced alcohol consumption in at-risk drinkers compared to controls, while also demonstrating that older adults can be engaged in brief intervention protocols and finding the protocols reasonable. Older patients who receive intervention in integrated care conditions have reduced drinking compared to those who are referred out. Most trials to date have been conducted in primary care settings using only one to four sessions that last from 15 to 60 minutes, including some telephone contacts and occasionally follow-up over 1 year.

Brief interventions for older adults are effective in mental health settings as well; thus, geriatric mental health care providers are encouraged to gain familiarity with brief intervention therapy both as a treatment tool and as a way to increase adherence to specialty treatment. Components of the intervention may utilize interactions outside of the clinic (e.g., mail or computer-based) which can help avoid many of the limitations of interventions targeting unhealthy drinking or substance use in clinical settings. For example, such interventions may: provide persons who do not regularly participate in the health care system access to important health information; offer the flexibility of use; allow the patient to maintain anonymity, thereby reducing potential stigma; provide a unique opportunity to individually tailor the intervention, and be far less costly than in-person interventions. Brief screenings are recommended by the U.S. Preventative Task Force as they have been shown to be practical in identifying people with unhealthy substance use and, coupled with brief interventions, can improve outcomes.

Psychosocial Interventions

Beyond screening and brief interventions, some older adults, such as those with moderate to severe use, may need more formal specialized substance use disorder treatment such as cognitive behavioral therapy, family-based therapies, and group and mutual-help support interventions. Few substance use disorder or co-occurring disorder treatments have been designed or studied specifically for older adults. Therefore less is known about best practices or recommendations. One study of older veterans found that individuals who completed a 16-week relapse-prevention group intervention, including cognitive-behavioral and self-management approaches, were more likely to be abstinent at a 6-month follow-up than noncompleters. Another study that included older adults (7% were age 60 or over) demonstrated the effectiveness of three different manual-driven individual psychological treatments (cognitive behavioral therapy, motivational enhancement therapy, and 12-step facilitation) that spanned 12 weeks. In this study, alcohol consumption was reduced 1 year post-treatment in adults with alcohol dependence.

Recommendations for treatment modification for older adults include attending to age and generational factors, psychosocial stressors, and cognitive and physical limitations. Generational factors may affect beliefs and attitudes toward substance use ranging from moralistic failure to cultural permissiveness. Developmental factors facing older adults often include the death of friends and family members, role changes in occupational and home settings, and normal age-related declines in physical and cognitive abilities. Flexible treatment modalities that offer transportation, in-home, or telehealth services are often needed for older adults who need accommodations. Similar to substance use treatments with younger adults, involving family members/caregivers, strengthening or expanding nonsubstance-using social networks, and addressing comorbid psychiatric conditions is often essential to recovery.

Twelve-Step Recovery Programs

Community-based programs for many years have centered on the traditional 12-step peer support model of recovery and rehabilitation, which includes mutual support and encouragement to help group members achieve and maintain sobriety. Studies have shown that older adults engage in and attend 12-step programs (e.g., Alcoholics Anonymous including Seniors in Sobriety, Narcotics Anonymous, Self-Management and Recovery Training [SMART], Women for Sobriety) with comparable frequency to other age groups. On the other hand, the degree of involvement in the programs has been shown to be less in older adults, and the likelihood of engagement in subsequent formal aftercare is reduced. The 12-step model has clearly been successful for many individuals; however, more treatment options are available now than there were when 12-step programs were developed. In addition, certain factors need to be considered, including perceived stigma, level of comfort disclosing personal information in a group setting, the degree to which age-appropriate issues are discussed, and transportation and health problems that may interfere with the likelihood of attendance.

Moderators and Correlates of Treatment

Certain factors may impact treatment response and adherence in older adults receiving treatment. Age-appropriate treatment is considered important in improving treatment completion and attendance rates at group meetings as compared to treatments that do not consider the unique aspects of aging. Characteristics of age-sensitive treatment include: being supportive and nonconfrontational, flexible, sensitive to gender differences, sensitive to cultural differences, holistic, and focused on coping and social skills. Older adults in a study of male veterans with alcohol problems randomly assigned after detoxification to age-specific or standard mixed-age treatment were 2.9 times more likely at 6 months and 2.1 times more likely at 1 year to report abstinence when in the age-appropriate treatment group. Programs that offer treatments specific to age (e.g., Smokefree60+, AA for the Older Alcoholic) should be considered first for older patients.

Matching the treatment to the patient also affects treatment outcome, although this has not been well evaluated in older adults. In one study of older primary care patients who were at-risk drinkers, 60.4% of patients referred to an integrated care model using a brief intervention modality attended at least one session versus 33% of patients referred to specialty care. This result occurred despite the elimination of copayments, availability of insurance claims at most sites, and appointment availability within 2 weeks of the initial assessment.

Certain patient-level characteristics may also impact treatment outcomes. At a 6-month follow-up assessment of patients treated at a private outpatient chemical dependency program, older women with severe AUD were significantly more likely to report abstinence from drugs and alcohol for the previous 30 days than men (79.3% vs. 54.0%). Among patients who were not abstinent, men reported a mean of four heavy drinking days, whereas women denied any heavy drinking. Favorable outcomes for older adults have also been associated with longer treatment retention and the absence of social network members who encourage substance use.

Intensive Outpatient Programs and Partial-Hospitalization

Each year more older adults are admitted to the hospital for substance use disorder treatment. However, treatment services outside of the hospital have failed to keep up. Few substance use treatment programs (approximately 18% of 14,000) provide services designed specifically for older adults, and most that do are hospitals or affiliated with inpatient psychiatric services. IOPs and PHPs are an important component of the continuum of care for the treatment of substance use disorders, but few offer services directed at older adults, and several have histories of excluding this age group. There are no research studies examining the utilization of a stepped approach for older adults with substance misuse.

IOP and PHP programs vary widely but generally include at least 9 hours of treatment per week and cover comprehensive assessment, medical and psychiatric treatment, individual/family/group therapies, 24-hour crisis services, and case management and discharge planning. When treating older patients, IOP and PHP programs need to be actively involved in local aging services, including residential care facilities and adult day health centers.

FUTURE DIRECTIONS

In the past 5 years, significant work has been done to address substance use, its consequences, and its long-term effects in the older population. Some of this work has been necessary as those in middle age transition to older age groups, and clinicians become more astute in identifying the impact of substance use on the overall physical and mental health of older adults. Even so, there continues to be a need for improved research to decrease the knowledge gap to understand the etiology and neurobiology of addiction for this population. Future studies, including individuals over the age of 65, are necessary to improve the understanding of treatment outcomes in older adults, including the impact of nutrition, vitamin supplementation, and comorbid medical illnesses. Further research is needed to validate DSM-5 diagnostic criteria for substance use disorders in older adults and to define the point at which patients with substance misuse should be treated in specialty addiction care as opposed to primary care or general geriatric mental health clinics. With the aging cohort and substance misuse pattern, more attention needs to be paid to prescription medication overuse and other illicit substance use and their impact on the older population. The expansion of the knowledge base on the potential risks and benefits of marijuana use and misuse in the geriatric population, given the current trend of legalization and expanding use, will be important. There may be a need for age-specific substance screening tools that can address the limitations of our current screening process in primary care settings. These tools should pay special attention to the interplay between substance use and normal and pathologic aging processes. As the population continues to age, the impact of higher incidences of diagnoses like ADHD needs to be monitored for potential misuse of prescription stimulants. Additionally, as novel treatments like ketamine and hallucinogenic agents like LSD become more common, how they may be misused by older adults must be reviewed over time.

55.4 Treatment of Psychiatric Disorders

55.4a Geriatric Psychopharmacology: General Principles

Bruce G. Pollock, M.D., Ph.D., F.R.C.P.C.

Pharmacokinetic and pharmacodynamic changes associated with aging and illness render older patients more sensitive than younger adults to the adverse effects of medications. Importantly, psychotropics are among the most common medications associated with preventable adverse drug events among the aged. Those 65 years and older, who represent 16.5% of the U.S. population, consume more than 40% of all prescription medications. Approximately one-third of people over age 60 are taking ≥5 prescription drugs. Additionally, they take on average four over-the-counter drugs or herbal preparations. All of this polypharmacy puts them at particular risk for drug–drug interactions.

Preventable drug interactions, inappropriate medications, excessive dosages, and unrecognized adverse drug reactions all contribute substantially to morbidity and mortality. Prescribing cascades occur when side effects from one medicine are treated with another medication. It is not uncommon for a prescriber not to be aware of all the medications a patient is taking. For these reasons, it has been observed that the most common treatable illness in older patients is iatrogenic and carefully stopping or reducing dosages (deprescribing) is often indicated.

Despite, or perhaps because of, their extensive medication use, the old are often excluded from clinical and regulatory trials. Without randomized, prospective drug trials, it is not truly possible for clinicians to decide whether a treatment is efficacious or even harmful. The absence of controlled studies makes it difficult to determine the optimal drug class or drug within a class for treating older adult psychiatric patients. For example, there were limited and somewhat contradictory anecdotal reports on the efficacy and safety of IV ketamine in older adults. However, 194 subjects over age 65 years were included in a double-blind, randomized trial of esketamine (Spravato), and no significant improvement was found in this age group compared to placebo, a fact that was included in the label. Similarly, when manufacturers of atypical antipsychotics were seeking an indication for psychiatric symptoms accompanying dementia, sufficient pooled placebo-controlled data were available to enable the FDA to determine that these medications increased mortality. Encouragingly, there has been continued progress in pharmacotherapy trials for late-life depression and generalized anxiety disorder as well as for the cognitive and psychiatric symptoms accompanying Alzheimer disease.

Although older adult patients frequently require lower doses of medications to mitigate side effects, age, alone, does not entirely guide appropriate dosage. Often, there is greater physiologic variation among individual older adults than there are group differences between young and old. It is important to consider individual patient characteristics, such as cardiovascular or renal function and genetic and acquired differences in body composition or drug metabolism, together with a drug’s physicochemical properties.

In addition to using rational pharmacotherapy, the physician must form an alliance with patients and their families to improve adherence to treatment. Nonadherence with therapy is a major problem for psychiatric patients, and this dilemma is exacerbated with age. The cost and complexity of medication regimens, inherent to the multiple illnesses of the aged, are further complicated by communication difficulties arising from impaired hearing, cognitive impairment, and language or cultural differences.

PHARMACOKINETIC CONSIDERATIONS

Pharmacokinetics provides a way of describing and predicting drug concentrations in plasma and various tissues over time. It has been estimated that 70% to 80% of adverse drug reactions are dose, and therefore concentration, related. Concentration relationships for adverse effects were clearly evident with tricyclic antidepressants (TCAs) and neuroleptics. Cholinesterase inhibitors have been associated with dose-related, cholinergic (nausea, vomiting, diarrhea) side effects, which can be particularly severe if doses are escalated too rapidly, or if cytochrome P450 (CYP) 3A4 metabolism is inhibited for those treated with donepezil (Aricept) or galantamine (Reminyl). For newer antidepressants and antipsychotics, explorations of drug concentration variability, let alone response relationships, were deemed unnecessary. Nonetheless, therapeutic indices for most drugs narrow with age and regulatory trials conducted in younger, healthier subjects are often conducted at or near their maximum-tolerated dosages to increase the probability of demonstrating efficacy. Failure to address this issue resulted in notable difficulties with the introduction of bupropion (Wellbutrin) and clozapine (Clozaril) (seizures at high doses), as well as fluoxetine (Prozac) and risperidone (Risperdal) (agitation, akathisia, extrapyramidal syndromes with excessive doses) in older patients. Olanzapine (Zyprexa) has shown a curvilinear dose–response relationship for treating older adult patients and quetiapine (Seroquel) is currently used over a wide dose range in older adults. In fact, more than 25% of neuropharmacologic drugs introduced in the past two decades have undergone recommended postmarketing dosage reductions for safety reasons.

The selective serotonin reuptake inhibitors (SSRIs) are first-line treatments for depression in older adults. Although they have relatively flat dose–response curves, unnecessarily high SSRI drug concentrations may increase side effects and cost. For example, SSRI plasma concentrations have been linearly associated with adverse cognitive and psychomotor effects in older subjects. Dose-dependent effects of SSRIs have also been reported for fragility fractures, falls, and decrements in bone density. Concern has also been raised about dose-dependent QT interval prolongation with citalopram (Celexa) in those older than age 60 or who are poor CYP 2C19 metabolizers.

It is important to appreciate the critical lack of pharmacokinetic information relevant to the majority of older adults encountered in clinical practice. The limited information that does exist for older subjects is largely derived from “classic” or “two-stage” pharmacokinetic modeling. Although single- and multiple-dose pharmacokinetic studies are a standard part of phase I drug development, they are almost exclusively carried out on young, physically healthy, unmedicated men. For example, the only published geropharmacokinetic data on the disposition of fluoxetine (which has a geriatric indication) is limited to a study of single doses in 11 healthy subjects (ranging in age from 65 to 77 years). Traditional pharmacokinetic methodology requires an intensive sampling regimen (i.e., a large number of precisely timed samples) usually obtained from a small number (e.g., 6 to 12) of volunteers. The pharmacokinetic parameters are determined for each individual separately and average pharmacokinetic parameters are calculated as the mean of the individually determined parameters. Single-dose studies often fail to provide accurate estimates of pharmacokinetic parameters for older adults. Multiple-dose kinetic studies are especially important to detect nonlinear phenomena wherein metabolic clearance ceases to be proportional to dose.

An alternative method is that of population pharmacokinetics using mixed-effects modeling. This statistical approach permits identification of individual and overall population pharmacokinetic parameters based on only a few samples per subject and using each data point to inform the entire analysis. Because a greater number of typical patients are evaluated, the results are much more applicable to clinical practice than those of traditional pharmacokinetics. Incorporating population pharmacokinetic analyses into clinical trials with older subjects may prove to be a significant addition to the ability to determine sources of variability in psychotropic plasma concentrations and response in older adults, particularly those with medical comorbidity.

Age-associated pharmacokinetic differences may be due to changes in absorption, distribution, metabolism, or elimination of a drug.

Absorption

With age, there is a decrease in the rate of gastric emptying and intestinal blood flow. Most studies evaluating drug absorption, however, have shown no difference in the rate or extent of absorption in geriatric versus younger patients. Nevertheless, antacids, high-fiber supplements, laxatives, and the cholesterol-binding resin cholestyramine (Questran) may significantly diminish the absorption of medications, such as TCAs and anticonvulsants. Drugs with anticholinergic properties may decrease absorption of L-dopa (Larodopa), owing to delayed gastric emptying in conjunction with the gastric metabolism of L-dopa. The potential gain in compliance achieved by administering medications at the same time should be weighed against the possibility of drug interactions in the absorption phase.

There is increasing interest in the genetic differences and drug interactions affecting functioning of the important drug efflux transporter, P-glycoprotein (MDR1), which can transport a large number of clinically used drugs out of the intestine, thereby playing a significant role in absorption. For example, variants in the ABCB1 gene, which encodes P-glycoprotein, have been found to influence the bioavailability of digoxin (Lanoxin). P-glycoprotein can be induced by carbamazepine (Tegretol), and inhibited by calcium channel blockers as well as macrolide antibiotics.

Distribution

Clinicians frequently overlook the fact that a drug’s half-life is directly proportional to its apparent volume of distribution. Adipose tissue increases from 33% of body mass in younger women to 48% in the old, and from 18% to 36% in men. Therefore for drugs that distribute in body fat (the vast majority of psychotropics), the volume of distribution will increase with age, leading to a longer half-life and drug accumulation. For water-soluble drugs, such as lithium or digoxin, volumes of distribution will be diminished in older patients, reducing the margin of safety (i.e., transient increases of these drugs' plasma concentrations will not be buffered to the same degree in older adults). Lipid-soluble benzodiazepines (e.g., diazepam [Valium] and clonazepam [Klonopin]) with long half-lives have been associated with an increased risk of falls and hip fractures in contrast to more water-soluble benzodiazepines with intermediate half-lives, such as lorazepam (Ativan).

The volume of distribution is also affected by the extent of drug bound to plasma proteins. Age-associated illness may cause reductions in serum albumin and possible increases in α-1-acid glycoprotein. The majority of psychotropics are transported in the blood extensively bound to these plasma proteins. Drug displacement interactions from plasma proteins were previously the subject of considerable concern because the protein-bound drug acts as an enormous, pharmacologically active reservoir. It is now recognized that not only is free drug pharmacologically active, but it is also more available for metabolism and tissue distribution. Therefore, an increase in the absolute concentration of free drug, caused by reduction in plasma proteins or a displacement interaction, would be buffered and equilibrium rapidly reestablished. When plasma drug monitoring is used to adjust TCA or anticonvulsant doses, it should be appreciated that the total drug concentrations (free + protein bound) are usually reported. In the face of hypoalbuminemia or a displacement interaction (e.g., phenytoin and aspirin), the total drug level may appear low and doses may, in consequence, be inappropriately increased. If the displacing drug also causes inhibition of drug metabolism (e.g., valproic acid [Depakote] and aspirin), total drug levels may appear to be acceptable, while free-drug concentrations are in fact significantly elevated. The use of unbound (free) drug levels in these situations has been found to be essential for lidocaine (Xylocaine), theophylline (Theo-Dur), valproic acid, phenytoin (Dilantin), and digitoxin (Crystodigin).

The blood–brain barrier forms an interface between the circulating blood and the brain and possesses various carrier-mediated transport systems for small molecules to support and protect central nervous system (CNS) function. For example, the blood-to-brain influx transport systems supply nutrients, such as glucose and amino acids. Age and illness, such as diabetes, may affect the integrity of the blood–brain barrier, increasing the drug exposure of the brain. P-glycoprotein, located at the luminal membrane of endothelial cells, functions as a clearance system for drugs entering the brain as well as for metabolites and neurotoxic compounds produced in the brain. Drugs recognized by these transporters are expected to show lower blood–brain barrier permeability. Examples of drugs now known to be substrates for P-glycoprotein include digoxin, erythromycin (Ery-Tab), lidocaine, morphine (Astramorph), nifedipine (Adalat), nortriptyline (Pamelor, Aventyl), propranolol (Inderal), risperidone, and verapamil (Calan). Several P-glycoprotein substrates may also inhibit its function, such as erythromycin, risperidone, and verapamil, permitting greater CNS penetration.

Metabolism

The purpose of drug metabolism is to transform lipid-soluble compounds into more water-soluble derivatives that can be more effectively eliminated and may be less active pharmacodynamically. Biotransformation of drugs is categorized as belonging to either phase I (oxidation or reduction) or phase II (conjugation). A large group of heme-containing enzymes, which vary in substrate preferences, collectively called CYP enzymes, is responsible for oxidative (phase I) drug metabolism. As more is learned about both the diversity and specificity of the CYP enzymes, a structure is emerging for categorizing potential drug–drug interactions and possible age-associated changes. Available evidence suggests that there is not a uniform age-associated decline in the quality of activity of these enzymes. Nonetheless, reductions in hepatic mass and blood flow with aging place greater emphasis on interindividual differences in drug metabolic capacity. These metabolic differences may be genetic or the result of interactions from multiple medications. Isoenzyme specificity suggests that inhibition or induction of a given CYP will affect all drugs metabolized by that specific enzyme. A drug may act as a substrate for one CYP at a time or simultaneously for more than one. A drug can act as both a substrate and a competitive inhibitor for the same isozyme, or it can act as a noncompetitive inhibitor for a different enzyme.

CYP 2D6 is the isozyme specifically responsible for hydroxylation of many antidepressants (e.g., nortriptyline, desipramine [Norpramin, Pertofrane], duloxetine [Cymbalta], paroxetine, venlafaxine [Effexor], and vortioxetine [Brintellix]) and several antipsychotics (perphenazine [Trilafon], thioridazine [Mellaril], brexpiprazole [Rexulti], iloperidone [Fanapt], and risperidone). Approximately 7% of the Caucasian population are genetically poor 2D6 metabolizers, which has been shown to impact on nortriptyline doses and adverse effects of perphenazine in older patients. Concern has also been raised about the potential cardiotoxicity of venlafaxine in poor 2D6 metabolizers or those taking concomitant diphenhydramine (a CYP 2D6 inhibitor). Studies conducted in older, unmedicated volunteers have not found an age-associated decline in CYP 2D6 activity. Nevertheless, many drugs commonly used by older patients competitively (e.g., perphenazine) or noncompetitively (e.g., paroxetine, fluoxetine, bupropion) inhibit this enzyme, leading to potentially significant interactions. The CYP 2D6 mediated metabolism of dextromethorphan and its inhibition by quinidine has led to the introduction of a combined product (Nuedexta) for the treatment of pseudobulbar affect.

CYP 2C19 is responsible for the metabolism of diazepam, mephenytoin (Mesantoin), citalopram, escitalopram (Lexapro), and omeprazole (Prilosec), as well as several barbiturates. In addition, the demethylation of tertiary TCAs is also partly dependent on 2C19. The incidence of the poor metabolizer phenotype in a young Caucasian population is approximately 3% but was 18% in a Japanese sample. There is some evidence that 2Cl9 functioning may decline with age. CYP 2C19 is responsible for metabolizing the narrow-therapeutic–index drugs phenytoin, tolbutamide (Orinase), and warfarin (Coumadin) and is inhibited by fluvoxamine (Luvox) and fluoxetine. Clopidogrel (Plavix) is an anticoagulant which requires 2C19 metabolism to be an active agent, It is mainly used to ensure patency after stent procedures. Given the high proportion of Asians in Hawaii who are poor CYP 2 C19 metabolizers, it was found that there were a disproportionate number of stent failures in Hawaii.

CYP 3A4 is the most prevalent drug-metabolizing enzyme and is responsible for metabolizing the most medications. Because it is normally a high-capacity enzyme, serious and surprising toxicity has occurred when the 3A4-mediated clearance of terfenadine (Seldane), astemizole (Hismanal), cisapride (Propulsid), midazolam (Versed), triazolam (Halcion), mibefradil (Posicor), and cerivastatin (Baycol) was diminished. Also, because hepatic metabolism of CYP 3A4 drugs is typically so rapid, many of these drugs are perfusion limited (i.e., dependent on hepatic blood flow, which may decline by 40% between ages 25 and 65 years). Therefore, it often appears that drugs specifically metabolized by CYP 3A4 decline with age—for example, alprazolam (Xanax) and triazolam clearances in older adults are only 50% to 80% of those in young adults. In particular, gender- and age-related pharmacokinetic differences have been demonstrated for several 3A4-typed drugs, such as sertraline (Zoloft), mirtazapine (Remeron), and nefazodone (Serzone). CYP 3A4 activity may be inhibited by grapefruit juice, protease inhibitors, “mycin” antibiotics, and “azole” antifungals. For example, pimavanserin (Nuplazid) concentrations are substantially increased by ketoconazole (Nizoral).

Among antidepressants, nefazodone and fluvoxamine are the most potent inhibitors, followed by fluoxetine, through its demethylated metabolite. The very long half-life of norfluoxetine may result in interactions occurring many weeks after initiation of fluoxetine. Similarly, the inhibition of the CYP 3A4-mediated clearance of “statins,” resulting in muscle weakness, may be misattributed in depressed patients. The 3A4 enzyme also may be induced by other drugs, such as carbamazepine, phenytoin, topiramate (Topamax), modafinil (Provigil), barbiturates, steroids, and St. John’s wort, increasing the risk of therapeutic failure for CYP 3A4 drugs. Many CYP 3A4 inhibitors (e.g., verapamil) and inducers (St. John’s wort) also have been found to interact at the P-glycoprotein drug transporter, amplifying their CYP 3A4-mediated effects.

CYP 1A2 metabolizes clozapine, olanzapine, fluvoxamine, asenapine (Saphris), and theophylline and contributes to the demethylation of some tertiary TCAs. This isozyme is induced by cigarette smoking and eating cruciferous vegetables and charcoaled meats, as well as by certain medications, such as omeprazole and phenobarbital (Luminal). Estrogen replacement therapy in postmenopausal women has been found to inhibit CYP 1A2 metabolism, whereas treatment with growth hormone causes induction. Inhibition and induction magnify an already marked, 60-fold variation in 1A2 activity. This degree of metabolic variation mandates that theophylline and clozapine be closely monitored.

There is more limited information about CYP 2B6, which substantially metabolizes bupropion. In vitro evidence has suggested that fluoxetine, paroxetine, and sertraline may cause CYP 2B6 inhibition. Given bupropion’s risk of concentration-related seizures and the frequency of its use with SSRIs, this may be of potential concern.

Beyond oxidative metabolism, phase II metabolism in older patients has been a neglected area for systematic study. In general, drugs such as lorazepam and oxazepam (Serax) accumulate less than more lipid-soluble drugs and undergo single-step conjugative elimination. Glucuronidation, however, may not be an immutable process, being significantly affected by malnutrition. Despite the common assertion that phase II metabolism does not change with age, significant reductions in oxazepam’s elimination have been found in those older than 80 years.

Excretion

The average glomerular filtration rate decreases by 50% between the ages of 20 and 70 years. Age alone, however, cannot be used to predict renal function, because at least one-third of older patients may maintain relatively stable renal function. Serum creatinine may not appear elevated in the face of declining renal function because there is often a decline in muscle mass, the major source of creatinine, with age and debilitation. Minimally, the use of estimates from standard nomograms or equations should be used to estimate creatinine clearance, given that it is often impractical to collect a 24-hour urine sample. Decline in renal clearance may directly affect excretion of such medications as lithium, gabapentin (Neurontin), pregabalin (Lyrica), topiramate, amantadine (Symmetrel), paliperidone (Invega), memantine (Namenda), rivastigmine (Exelon), and desvenlafaxine (Pristiq). The clearance of hydrophilic (polar), psychotropic drug metabolites may also be reduced in older patients. Paliperidone is the active 9-OH metabolite of risperidone and accumulations of active hydroxylated metabolites of antidepressants, such as nortriptyline, bupropion, and venlafaxine, have been observed in older patients with uncertain clinical consequences.

The nonsteroidal anti-inflammatory drugs (NSAIDs) and angiotensin-converting enzyme (ACE) inhibitors reduce lithium's clearance (possibly through effects on renal blood flow). Given the widespread use of these medications in older adults and their increased risk of lithium toxicity, this potential interaction deserves emphasis. Low-salt diets and the possibility that SSRIs may cause inappropriate antidiuretic hormone secretion, with concomitant hyponatremia, are additional sources of interactive complications with lithium.

PHARMACODYNAMICS

As patients age, there is a general reduction in homeostatic mechanisms (e.g., postural control, orthostatic circulatory responses, thermoregulation, visceral muscle function, laryngeal reflexes, hypoxic responses, cognitive function). This reduction may interfere with adaptation to environmental changes and may manifest as adverse drug experiences. All psychotropics may increase risk of falls and hip fractures and may increase cognitive impairment. Physiologic (postural or action) tremors may be exacerbated by numerous drugs, including β and dopamine agonists, xanthines, valproic acid (valproate), steroids, and antidepressants. Reduced β-receptor sensitivity with aging contributes to diminished baroreceptor reflex responses, whereas coronary artery disease, reductions in the heart's intrinsic sinus rate, and damage to conduction pathways predispose to arrhythmias. The fact that SSRIs may exacerbate bradycardia should also be borne in mind. In older patients chronically treated with antipsychotics, the prevalence of obesity, poor nutritional status, and increased triglycerides may contribute additional cardiovascular risk factors.

Specific receptor and neurotransmitter changes associated with senescence, such as reductions in dopamine or acetylcholine content, result in increased sensitivity to D2 antagonists and antimuscarinic agents. Side effects from conventional antipsychotics and tricyclics were common and frequently troubling in older patients. In particular, the association of these medications with significant cognitive impairment declines in activities of daily living, and significant falls (with concomitant risk of hip fracture) was of grave concern in the frail older adults. Prospective studies demonstrated that there was a very rapid and high incidence of onset of tardive dyskinesia in older patients taking conventional antipsychotics for relatively brief periods (cumulative incidence reported as 26% to 45% over 1 year). Although atypical antipsychotics are extensively used in older patients, meta-analyses of 17 controlled trials found that these medications increase mortality (4.5%) compared to placebo (2.6%) in older adults suffering from dementia within the relatively short duration of the trials conducted (typically 10 weeks). Moreover, the side effects of these medications may outweigh their potential benefits. Some of these side effects are concentration related, such as extrapyramidal symptoms with risperidone and anticholinergic symptoms with clozapine or olanzapine. Concentrations of atypical antipsychotics may be significantly affected by concomitantly administered medications that inhibit or induce CYPs IA2 (asenapine, clozapine, olanzapine), 3A4 (aripiprazole, iloperidone, quetiapine, ziprasidone), or 2D6 (aripiprazole, risperidone).

Two groups of drugs cause anticholinergic effects: those used therapeutically for their anticholinergic properties (e.g., oxybutynin [Ditropan], benztropine [Cogentin]) and those that have anticholinergic effects that are incidental to their main actions (e.g., amitriptyline [Elavil], cimetidine [Tagamet], digoxin, paroxetine). Peripheral manifestations of anticholinergic action include dry mouth, tachycardia, blurring of vision, urinary retention, and constipation. Common difficulties in older patients, such as constipation, xerostomia, glaucoma, and urinary retention, may be markedly exacerbated by even modestly anticholinergic medications. Anticholinergic effects on the CNS may range from subtle changes, such as mild confusion and impairment of recent memory, to physical decline. Patients with a dementing illness are most at risk from these central anticholinergic effects. Nonetheless, studies have found that even medications with modest anticholinergic effects are additive and affect cognitive performance in a wide cross-section of older adults. In fact, understanding of the nature of cognitive decrements associated with "normal" aging may be distorted by modest anticholinergic burden. It should also be noted that medications with prominent noradrenergic actions can also cause dry mouth, urinary retention in older men, and tachycardia, in addition to exacerbating hypertension and tremor.

Older patients have been found to require smaller doses of anticoagulants to achieve the same degree of anticoagulation as obtained in younger individuals. Although confounded by effects of other medications and hepatic dysfunction, increased sensitivity of older adults to anticoagulants is probable. Anticoagulants figure prominently in drug-related morbidity and mortality. Genetic tests may, in the near future, help to detect the estimated one-third of patients with variants that make them slow metabolizers of warfarin (CYP 2C9) or more sensitive to its effects (vitamin K epoxide reductase activity [VKORC1]). Anticoagulant–antidepressant interactions may be pharmacokinetic as well as pharmacodynamic. Fluvoxamine poses a risk for a pharmacokinetic interaction through inhibition of CYP 2C9, reducing the clearance of warfarin's active S-enantiomer. In addition, inhibition of CYPs 1A2 (fluvoxamine), 2C19 (fluvoxamine, fluoxetine), and 3A4 (fluvoxamine, fluoxetine) will cause R-warfarin to accumulate, which also contributes to reduced S-warfarin clearance. However, increased bleeding times with SSRIs alone or in combination with anticoagulants also may be possible owing to SSRIs' effects on platelet serotonin and thereby attenuating aggregation. Concurrent therapy need not be avoided, but close monitoring is advisable whenever an SSRI is combined with warfarin. Both concerns (increased risk of gastrointestinal bleeding in older adults) and potential benefits (protective effects against myocardial infarction in smokers) have been raised by epidemiologic studies of SSRIs.

In addition to problems that may be anticipated, because most of the data on a new drug's effects have been obtained in younger patients, unexpected side effects are not infrequent in older adults. In older patients, SSRIs and venlafaxine have been associated with the syndrome of inappropriate antidiuretic hormone secretion (SIADH). Although SIADH is a rare adverse effect of many psychotropic medications, the majority of reports of antidepressant-induced SIADH have involved patients older than 65 years. In an analysis of 760 reports of hyponatremia associated with SSRIs, the median time to onset of the hyponatremia was 13 days (range, 3 to 120 days). SSRIs in older patients also have been associated with Parkinsonism or worsening of motor disability in patients who have idiopathic Parkinson disease. It is possible that this is a result of serotonergic-influenced reduction in dopaminergic transmission in a population with diminished dopamine reserves. Concern has also been raised recently from large population studies. One found chronic use of SSRIs associated with a twofold increased risk of fragility fractures and lower bone mineral density. Another associated SSRI therapy with a nearly fivefold increased risk of completed suicide in older patients during the first month of treatment compared with other antidepressants. This finding is somewhat paradoxical since the combined results of regulatory studies with SSRIs suggested an attenuation of suicidal ideation in older subjects early in treatment. Although the absolute risk of suicide may be low, there is a clear need for close monitoring of older patients, especially males with comorbid medical illness.

In addition to the CYP isozymes discussed previously which may impact on pharmacogenetics, There are genetic polymorphisms that may impact response at drug targets. The best studied is SLC64A which incodes for the serotonin transporter promoter which in turn determines the availability of serotonin transporters which are the sites of action of SSRIs. Those possessing the long form (L/L) of SLC64A may have a more rapid and robust response to an SSRI as compared to those with the S/S genotype.

Finally, a genetic polymorphism in the human leucocyte HLA antigen B*1502 has been linked to severe dermatologic reactions such as Stevens–Johnsons syndrome in those prescribed carbamazepine, oxcarbazepine (Trileptal), lamotrigine (Lamictal), and phenytoin.

Among the greatest threats to successful pharmacotherapy in older patients are patient nonadherence with medication regimens and drug–drug interactions. High-risk medications, including anticoagulants, antihypertensives, and antiarrhythmics, have been consistently emphasized in long-term, comprehensive surveys of adverse drug reactions in older patients. Physicians need to be particularly vigilant and knowledgeable when psychotropics are coprescribed with these high-risk medications. As patients age, pharmacodynamic changes and concomitant illness will significantly alter their response to medication. Psychiatrists treating older patients should use a set of routine procedures as follows: (1) identify patient risk factors, such as medical status, use of high-risk medications, and alcohol use; (2) take a thorough drug history involving caregivers and pharmacists, being sure to include over-the-counter medications and update regularly in a prominent place in the patient's record; (3) educate patients and caregivers about their medications and dosing regimens and monitor adherence; (4) be knowledgeable about drug actions, interactions, and clearance; (5) use the lowest effective doses and carefully graduated increases, and avoid unnecessary polypharmacy, but do not undertreat; (6) frequently reassess psychomotor function, including mental status and balance, as well as orthostatic blood pressures and specific laboratory tests when appropriate; and (7) if there is a deterioration in patients' physical or cognitive states, always suspect an adverse drug reaction.

FUTURE DIRECTIONS

Developments in clinical trial design and the completion of large effectiveness trials serve further to heighten concerns about the efficacy and side effects of currently available pharmacologic therapy for the symptomatic relief of psychiatric symptoms in older adults.

Controlling for heterogeneous drug exposure in conjunction with improved understanding of the genomic basis of cognitive, mood, and psychotic dysfunction and its complex interactions with age-related ischemic and other environmental CNS changes, may lead to more targeted molecular therapeutics. Regulatory policy and public health initiatives must be amplified to increase the representation of typical older subjects in clinical trials and improve the relevance of the therapeutic evidence base.

Recently, there have been a number of significant rigorous trials conducted by pharmaceutical companies for disease-modifying agents for Alzheimer disease. Recently, there has been promise shown for the first time in delaying the progression of Alzheimer's by three anti-amyloid drugs, aducanumab (Aduhelm), lecanemab (Leqembi), and donanemab. Federally funded projects focused on treating the agitation accompanying dementia are proceeding. Also, small pharmaceutical companies have taken an interest in this area and there are number of phase 3 trials which are ongoing at the time of writing. It is to be hoped that we will soon have evidence-based alternatives to the extensive use of lethal antipsychotics for this tragic consequence of dementia.

For medications approved for release, it is to be hoped that postmarketing reporting and the cross-linking of electronic medical and pharmacy records will continue leading to improved prescribing for older psychiatric patients.

ACKNOWLEDGMENT

55.4b Antidepressants and Mood Stabilizers

CARL SALZMAN, M.D.

GOALS AND RATIONALE FOR THE PHARMACOLOGIC TREATMENT OF DEPRESSION IN LATER LIFE

Clinically significant depression in late life is a disorder that encompasses a spectrum of severity ranging from debilitating major depression that has serious consequences for the life of the patient to minor depression that can impair quality of life. Most depressed older individuals have had prior depression, sometimes many, and sometimes as part of a bipolar spectrum. As in younger people, the course of depression in older adults is characterized by exacerbations and remissions as well as chronicity. Multiple pathways contribute to late-life depression, including neurobiologic and psychological factors, physical illnesses and their treatments, cognitive and sensory decline, as well as common social and economic problems. Depression is common in medical diseases and may be linked to inflammatory cytokines. First-onset depression in an older adult is usually associated with the increasing presence of cortical white matter hyperintensities and cognitive impairment. Depression also commonly accompanies late-onset dementias. Clinicians should also be alert to other medications and alcohol causing or exacerbating depressed mood. Among community-dwelling residents over the age of 65, approximately 13% to 27% may suffer from subsyndromal depression, 15% exhibit depressive symptoms but do not meet diagnostic criteria for any disorder, 1% to 2% suffer from major depression, and 2% are living with dysthymia. The prevalence of depression in all forms is much higher in nursing homes and in hospitals.

There appears to be considerable heterogeneity in the onset and course of late-life depression. Diagnostic patterns are also variable among older individuals. True clinical depression should be distinguished from unhappiness and grief that can be part of normal aging. When symptoms are serious enough to impair normal age-appropriate mood and behavior and persist for more than 2 weeks, the diagnosis of a treatable late-life depression should be considered. Clues to depression include frequent medical visits with persistent complaints of pain, headache, fatigue, and insomnia; and high utilization of services. Additional clues to depression in older adult hospitalized patients include delayed recovery, treatment refusal, and problems with discharge. In the nursing home patient, depression should be suspected in the presence of apathy, failure to thrive, agitation, and delayed rehabilitation. Older individuals who are depressed may also have structural and functional changes in the brain, including ventriculomegaly, white matter hyperintensities, cortical thinning, and vascular changes. Apathy, as part of late-life depression, is particularly resistant to antidepressant treatment and may be a result of changes in cortical thickness and communication between elements of the salience network.

Depression in later life should be treated because it usually persists in the absence of treatment, causing distress to patients' caregivers, as well as leading to excess healthcare use and increased substance abuse. Mood disorders also play a greater role in the suicides of older adult patients than in those of younger patients; the group at the highest risk for suicide is white males aged 80 to 84 years. A majority of suicide victims visit a primary care physician in the last month of life.

Aging is associated with many important changes in life, such as the loss of loved ones, retirement, and changes in living arrangements that may contribute to depression. For some depressed older individuals, psychosocial interventions and various forms of psychotherapy are available for treatments, although they have not been studied as intensively as pharmacotherapy. Music and pets are often helpful.

Pharmacologic treatment of depression in older adults may improve day-to-day functioning and self-care and can improve physical health and cognitive functioning. Although drug treatment benefits usually outweigh the risks, late-life depression is often untreated with medication, especially in frail older adults, either because the depression is not recognized or from fear that treatment will further damage an older individual. Poor medication adherence, concomitant substance use, and comorbid neurologic illnesses decrease response to medication for late-life bipolar disorder. The risks of no treatment or inadequate treatment, however, include chronic depression, increased cognitive impairment, worsening of physical illness, poor compliance with medical treatment, social impairment, reduced quality of life (satisfaction, ability to cope), and suicide. Anxiety is a common component of late-life depression, and high levels of anxiety may delay the response to antidepressant treatment. Although the research evidence for nonpharmacologic treatments is scarce, the few available studies, as well as clinical experience, suggest that for those older adults who cannot take medications or who prefer not to take a drug, nonpharmacologic treatments and interventions should be implemented.

The goals of pharmacologic treatment of both major and minor depressive disorders in later life include remission, if not substantial reduction, of depressive symptoms, as well as the prevention of relapse and recurrence. Hence, long-term use of antidepressants is probably the rule, not the exception. Treatment goals also include restoring psychosocial functioning, relieving excess disability, and improving patient compliance with other medical therapies that might be refused because of hopelessness or pessimism caused by depression. Antidepressants may also ease the adaptation to irreversible losses. Recent meta-analyses and extensive clinical experience suggest the greater efficacy of antidepressants compared with placebo in older adults. Expert consensus guidelines now recommend that antidepressant treatment should be combined with psychotherapy when possible. Since older individuals with mood disorders are often taking multiple medications, it is also necessary for the prescribing clinician to remain alert for possible adverse drug interactions. These will be discussed in each of the following sections.

PHARMACOLOGIC TREATMENT OF DEPRESSION

Antidepressants used to treat older depressed adults include the same drugs that are given to younger adults. The overall efficacy of antidepressants for the treatment of late-life depression is well established, although many, if not most older adult patients do not experience full remission from their depressive symptoms and may be more sensitive to side effects and drug interactions. In general, aging results in altered metabolism and excretion of some antidepressants, prolonging their effect. For example, the clearance of some antidepressants, such as citalopram, is delayed, causing drug accumulation and high blood levels. The sensitivity of the central nervous system to antidepressant drugs is also increased by age: most (but not all) older individuals are more sensitive to the therapeutic effects of antidepressants as well as their side effects. Since older individuals are often taking multiple medications, there is an increased risk of adverse drug interactions with antidepressants.

Accumulating data suggest that older adult patients respond as well to antidepressant treatments as younger adults. Data also suggest that the time to respond does not differ from younger adults, but clinicians often notice that it may require longer time periods to achieve remission or full therapeutic response. Response to treatment of late-life depression is associated with severity, current episode severity, and executive dysfunction. In frail older adults, treatment response to antidepressants may not differ from placebo response, suggesting that the older adult patient’s physical status may also predict response or nonresponse. The presence of anxiety is associated with increased severity of depression but does not affect response to antidepressant treatment. Antidepressants are sometimes given to older individuals with Alzheimer disease (AD), but the data for their usefulness is negative, and there may be anticholinergic side effects that might worsen dementia.

SELECTIVE SEROTONIN REUPTAKE INHIBITORS

Selective serotonin reuptake inhibitor (SSRI) antidepressants are now considered the first choice for the treatment of older adult depression because of their efficacy and favorable side-effect profile. Studies of SSRIs do not demonstrate the superior antidepressant efficacy of any one member of this class over another. Late-life depression associated with dementia, as well as with a medical illness, responds to SSRIs. Most SSRIs can be taken once daily, which increases compliance, especially for older patients who are taking multiple medications. Although SSRIs do not cause orthostatic hypotension, they have been implicated in an increased prevalence of falls in older adult nursing home residents. At therapeutic doses, they are less likely to cause cognitive impairment or anticholinergic and cardiovascular adverse effects. The limitations of these agents include nausea, headache, restlessness, sexual dysfunction, decreased heart rate, occasional insomnia, and occasionally inappropriate antidiuretic hormone secretion. Some SSRIs, especially fluoxetine, fluvoxamine, and paroxetine (and sertraline, to a lesser extent), interfere with cytochrome-metabolizing enzymes. Since hepatic metabolism is the primary route for drug detoxification and elimination, inhibition of these enzymes (especially CYP450 2D6 and 3A4) may raise the blood levels of other medications, causing unwanted side effects and toxicity. Medications whose metabolism may be inhibited include cardiac antiarrhythmic drugs, antidepressants and neuroleptics, some benzodiazepine anxiolytics, steroids, some antihistamines and antibiotics, and antifungal agents. Fluoxetine and paroxetine, in particular, are strong inhibitors of the metabolizing hepatic enzyme CYP450 2D6. This enzyme is necessary to convert tamoxifen to its active metabolite; inhibition by either of these SSRI antidepressants will prevent this conversion and render the tamoxifen useless. Citalopram and escitalopram do not affect hepatic metabolizing enzymes and may be less likely to cause drug interactions. For some clinicians, this lack of enzyme interaction suggests either of these two drugs is a first-choice SSRI antidepressant for older adults who may be taking other medications.

Examination of the role of polymorphisms of the serotonin transporter protein gene indicates that in older individuals (as in young adults), the “s” variant is associated with a decreased reduction in serotonin reuptake and a less robust response to SSRI antidepressants.

Starting doses of SSRIs should be low (paroxetine 10 mg, sertraline 25 mg, citalopram 10 mg, escitalopram, or fluoxetine 10 mg) followed by gradual dosage increases, particularly in those above age 75. Therapeutic dosages will vary, ranging from 20 to 60 mg a day of paroxetine, 50 to 200 mg a day of sertraline, and 10 to 60 mg a day of fluoxetine, citalopram, or escitalopram. Therapeutic blood concentrations of SSRIs are not available for routine clinical use. Studies of augmentation of an SSRI antidepressant with other medications such as methylphenidate, bupropion, thyroid, or estrogen have shown equivocal efficacy in older adults. However, recent data have demonstrated effective therapeutic augmentation of SSRIs with aripiprazole. Escitalopram has also been combined with the glutamatergic drug memantine (usually used for the treatment of AD) for augmentation of its therapeutic effect.

Newer antidepressants with selective serotonin reuptake inhibiting properties are now available. All are effective antidepressants; there are no data to suggest that any are superior to existing SSRIs. These drugs include vilazodone (given in the usual daily dose of 40 mg taken with food), which combines serotonin reuptake blockade with direct effects on synaptic serotonin receptors.

DUAL-ACTING ANTIDEPRESSANTS

There are 10 currently available antidepressants that enhance neuronal transmission in central nervous system mood-regulatory circuits by inhibiting the presynaptic reuptake of both norepinephrine and serotonin: venlafaxine, desvenlafaxine, duloxetine, milnacipran, levomilnacipran, mirtazapine, trazodone, nefazodone, vilazodone, and vortioxetine.

Venlafaxine, an inhibitor of noradrenaline and serotonin reuptake, is an effective and safe antidepressant for older adults. Compared with other antidepressants, it may induce slightly higher rates of remission of depressive symptoms in nonolder adults; data are scant for older adults. Patients respond to a relatively wide range of daily doses, and no dosage adjustment is necessary based on age. The use of venlafaxine entails several precautions. Headache and nausea may be minimized by using lower dosages of 25 mg daily and using the extended-release formulation, gradually titrating up to a therapeutic dosage. Venlafaxine may cause modest increases in diastolic blood pressure, which should be monitored. Venlafaxine use is not associated with drug interactions or enzyme inhibition. Desvenlafaxine is also available for the treatment of depression. This metabolite of venlafaxine is an effective antidepressant at 50 mg/day. Duloxetine is an effective antidepressant at doses similar to those used for younger adults (up to 60 mg/day). Its side-effect profile is mild, and there have been clinical reports that this medication (like other dual-acting antidepressants) may be helpful in controlling pain from arthritis or rheumatoid disorders. Milnacipran is an effective antidepressant for older adults at doses of 75 to 100 mg/day. At these doses, it does not adversely affect the cognitive function or psychomotor performance. Levomilnacipran is now available and is effective in geriatric patients at doses of 20 to 40 mg/day. This antidepressant is primarily cleared through the kidneys, so older patients with renal impairment probably should not be treated with this particular antidepressant. Mirtazapine, through its unique receptor activity, is also considered a dual-acting drug. Mirtazapine is an effective antidepressant in older adults at doses of 15 to 30 mg/day. However, it is quite sedating, so starting doses should be low; mirtazapine may be helpful as a sleep-inducing medication even in the absence of depression. A rapidly dissolving tablet is very useful for nursing home patients who have difficulty swallowing a pill.

Although not officially classified as dual-acting drugs, trazodone and nefazodone also affect both norepinephrine and serotonin neurotransmission. These drugs are weak serotonin reuptake inhibitors and are less commonly used to treat depression. Trazodone, however, is an effective drug for inducing sleep onset. Nefazodone strongly inhibits the CYP450 3A4 metabolizing enzyme;

it should not be prescribed together with benzodiazepine anxiolytics, steroids, antibiotics, antifungal medications, and certain antibiotics, and has been decreasingly used and available for the treatment of depression in all ages. When prescribed mood-stabilizing medications (antiseizure drugs such as carbamazepine, lamotrigine, and divalproex sodium), blood levels of the mood stabilizer may rise, producing unwanted side effects.

Vilazodone and vortioxetine are newer antidepressants that are available for clinical use. Research has been scant on the clinical efficacy of these two drugs in the depressed geriatric population. They appear to be equally effective with each other in older adults and as therapeutically effective as sertraline.

SSRIs and dual-acting antidepressants, such as venlafaxine but not tricyclic antidepressants, are associated with an increased rate of bone loss in older women, especially in the hip. This bone loss is associated with a two-fold increase in clinical fragility fracture since there is an increased risk of falls in nursing home residents who are taking SSRI (or tricyclic) antidepressants.

In general, these dual-acting antidepressants are not likely to produce serious drug interactions with other medications. It is good practice, however, to minimize the total number of medications that are coprescribed with these antidepressants and avoid using more than one antidepressant at the same time. Drugs that increase serotonin function may interact with these dual-acting drugs to produce a serotonin syndrome and should be avoided.

BUPROPION

Bupropion is an effective and safe antidepressant that is often prescribed to older patients because of its activating properties and relatively benign side-effect profile (no weight gain or significant anticholinergic properties). Advantages of bupropion include efficacy, especially in psychomotorically retarded older patients, and no adverse effects on cognition. Bupropion does not cause sedation and may even be stimulating for some older adult patients, which may interfere with sleep. Bupropion may be helpful in depressed older patients with Parkinson disease. However, because of its activating properties, bupropion may increase anxiety in some older individuals, especially those who are already anxious. Bupropion is a strong inhibitor of the metabolizing hepatic enzyme CYP450 2D6. This enzyme is necessary to convert tamoxifen to its active metabolite; inhibition by bupropion will prevent this conversion and render the tamoxifen useless. As with other antidepressants, starting doses should be lower than those recommended for younger adults, and dosage increments should be gradual.

TRICYCLIC ANTIDEPRESSANTS

Tricyclic antidepressants, nortriptyline, and desipramine, in particular, are effective medications for major depressive disorder in older adults. Blood levels of these two drugs necessary to achieve a therapeutic effect in older adults are the same as in younger adults, thus providing the clinician with a laboratory value to guide dosing. Hydroxy metabolites of the tricyclics are potentially cardiotoxic in older individuals and may be present at higher plasma levels than in younger adults because their renal excretion is decreased by advancing age. An electrocardiogram (EKG) can be used to monitor patients in order to avoid approaching cardiotoxicity, which is signaled by a widening of the QTc interval.

Annoying peripheral anticholinergic side effects of tricyclics, particularly constipation and dry mouth, can become severe problems in older adults leading to bowel obstruction and poor dental hygiene. Central nervous system anticholinergic side effects, which usually consist of decreased memory and attention, can progress to a delirious state with severe confusion, disorientation, and paranoid ideation. Orthostatic hypotension, another common adverse effect of tricyclic treatment of late-life depression, may increase the risk of falls; oversedation may interfere with participation in daytime activities.

To prevent these common tricyclic antidepressant side effects, relatively low starting doses with small dosage increments are usually employed. The prescribing maxim “start low (initial dose) and go slow (subsequent dosage increases)" applies to older individuals as a class of patients, although not necessarily to any individual patient.

Plasma levels of imipramine, desipramine, and nortriptyline can be routinely obtained. These levels correlate with therapeutic effects as well as with side effects. Prescribing clinicians who wish to use tricyclic should follow plasma levels of the tricyclic (preferably the secondary amines, desipramine, or nortriptyline) as doses are adjusted to the therapeutic range. Using these levels, along with an EKG to monitor the appearance of a potentially dangerous cardiac arrhythmia, provides the prescribing clinician with two sources of data to guide the use of these medications.

MONOAMINE OXIDASE INHIBITORS

Monoamine oxidase (MAO) inhibitors may be effective in depressed older patients. Their advantages include few anticholinergic effects and no effects on cardiac conduction. MAO inhibitors are potentially dangerous for older individuals and should not be used except by prescribing clinicians who have experience with these medications. The potential for toxic interactions between these drugs and other medications (e.g., serotonin-enhancing drugs; meperidine or other opiates, tricyclic antidepressants) or certain commonly eaten foods (e.g., aged cheese, pickled meats, and fish) is high in older adult population. Consequently, if these medications are to be used, they must be prescribed only to those older patients who are able to follow the dietary and drug interaction limitations.

For appropriate and compliant older patients, problem interactions with food and drugs can be minimized through patient education and collaboration among treating physicians. Limitations in their clinical utility include both hypotension and hypertension, insomnia, and somnolence. The starting dosages of tranylcypromine and phenelzine are 10 mg a day and 15 mg a day in two doses, respectively. In general, maximum dosages do not typically exceed 40 to 50 mg a day for tranylcypromine and 75 to 90 mg a day for phenelzine.

Transdermal selegiline (Emsam) is now available as a skin patch, although there is scant literature regarding its use in older adults. This

MAO inhibitor decreases the problems of drug and food interactions that may occur when high doses of the patch or the interacting medication or food are ingested.

STIMULANTS

Stimulants, such as methylphenidate (Ritalin), are not classified as antidepressants and should not be used as a solo medication to treat an older depressed individual. However, low doses of methylphenidate (2.5 to 5.0 mg/day in divided doses) may be helpful in activating a withdrawn, apathetic older patient, as well as increasing motivation and social participation. Methylphenidate may also enhance the therapeutic effect of antidepressants which have only produced a partial response. Low doses are not associated with tachycardia, hypertension, or cardiac toxicity; doses administered after 3 or 4 PM may interfere with sleep. Other activating drugs (modafinil, armodafinil) may also be used for mild activating effects. Stimulants and other activating drugs should not be given after 2 to 3 PM in order to avoid interfering with sleep onset at bedtime.

TREATMENT OF PSYCHOTIC DEPRESSION IN LATER LIFE

Psychotic depression is a severe illness with profound depressive symptomatology accompanied by delusions, often of somatic dysfunction, hopelessness, or guilt. Psychotic depression poses a health risk from progressive weight loss and exhaustion as well as from suicide, usually by violent means. For this reason, recognition and treatment of psychotic depression can be lifesaving. Both young and older patients with psychotic depression respond poorly to short-term treatment with antidepressants given alone. Combinations of antidepressants and antipsychotic medications are effective in psychotic depression in both controlled studies of younger patients and naturalistic treatment studies of older patients. Although tricyclics were the most frequently prescribed antidepressants in conjunction with an antipsychotic drug, clinicians are now using a combination of

SSRIs or dual-acting antidepressants together with atypical neuroleptics to reduce the side effects of older medications.

Electroconvulsive therapy (ECT), rapidly effective and safe, remains the treatment of choice for severe geriatric psychotic and treatment-resistant severe depressions. Concern over potential cognitive impairment from ECT, although often transient, has limited its usefulness. Recent data on a study of ultrabrief pulse width and right unilateral electrode placement demonstrated fewer neurocognitive adverse effects. When combined with venlafaxine in this older adult sample, cognition remained relatively modest or stable.

TREATMENT OF DEPRESSION ASSOCIATED WITH MEDICAL ILLNESS AND COGNITIVE IMPAIRMENT

The National Institutes of Health (NIH) Consensus Development Conference on the Diagnosis and Treatment of Depression in Late Life stated that “the hallmark of depression in older people is its comorbidity with medical illness.” Compelling evidence from placebo-controlled clinical trials indicates that antidepressant medications are efficacious in patients with common comorbid medical disorders as diverse as stroke, Parkinson disease, AD, cancer, ischemic heart disease, chronic obstructive pulmonary disease, and arthritis. It appears that all antidepressants are therapeutic, at least to some degree, even in rehabilitation units where treatment of depressed patients can facilitate recovery from acute illness or injury and in a residential care setting, where patients are characterized by extreme old age and the interacting effects of many of the common disabling medical disorders of later life. Until recently**,** tricyclic antidepressants were the most widely studied drugs for the treatment of depression associated with another illness. They have demonstrated safety and effectiveness for poststroke patients, as well as for older depressed patients with Parkinsos disease, cardiovascular illness, and cancer. However, interactions between tricyclic antidepressants and other nonpsychiatric medications used to treat medical or neurologic illnesses can make older patients highly vulnerable to the development of side effects. Thus, careful monitoring of both potential adverse effects and plasma concentrations is necessary to optimize the safety of these agents in frail older patients. SSRIs and other nontricyclics are now more widely used in order to avoid this potential for adverse drug events; SSRIs have been shown effective for depressed patients with cardiovascular illness, stroke, Parkinson disease, and cancer.

Depression and cognition intersect in two ways: older individuals with failing cognition or who are suffering from dementia commonly are depressed; depressed older individuals frequently complain of impaired memory and concentration. This interaction between depression and diminished cognitive function has been well studied. Regardless of whether the primary illness is dementia or depression, depression should be treated following the basic principles that apply to older patients. Medication use should be supervised, and caregivers should assess the benefits and monitor for adverse effects of treatment. Patients with dementia of Alzheimer type are highly sensitive to increased cognitive impairment from anticholinergic medications. Therefore, antidepressants with the lowest anticholinergic effects are preferred, which include SSRIs, low doses of bupropion, venlafaxine, mirtazapine, and vilazodone. Low doses of nortriptyline are sometimes helpful as well. Memory and concentration often improve as depression responds to medication; in mild to moderate degrees of dementia, successful antidepressant treatment can restore or even transiently improve memory and concentration. However, as dementia worsens, antidepressants may cause increased agitation and must be discontinued. The study by Lisanby et al. discussed above suggests that new ECT administration techniques combined with a dual-acting antidepressant may offer clinical improvement for a patient with late-life depression without further increasing cognition.

ESSENTIALS OF PATIENT MANAGEMENT

Several principles of clinical practice should guide the clinician who wishes to treat a depressed older individual. Careful psychiatric and medical diagnoses go hand in hand; older depressed individuals must be medically evaluated, especially for thyroid dysfunction and levels of B_{12} and folate. For some older people, this evaluation should include a neurologic examination to rule out Parkinson disease or dementia. It is well established that inflammation and inflammatory disorders are commonly associated with mood disturbance, especially depression. Chronic illnesses such as diabetes are also commonly associated with depression. Poststroke and postmyocardial infarction depressions are similarly well known, and failure to treat the depression may increase morbidity or subsequent mortality. A comprehensive list of all medications (prescribed or self-purchased), including herbs, holistic remedies, and homeopathic preparations, must be obtained since medication-induced (or worsened) depression is common in older adults. The clinician must also determine whether or not alcohol (or other drugs) is being used excessively or inappropriately before embarking on a treatment program. It may be necessary for the clinician to obtain this information from a spouse, child, or other sources, as the depressed older person may not offer an accurate history.

Treatment-Resistant Depression

Recurrent depressive illness often becomes progressively resistant to treatment as a person ages and has more recurrences. Consequently, the usual medication recommendations may be insufficient to achieve therapeutic response or remission. The use of ECT has already been discussed, and the use of ketamine in older adults is currently under investigation. Augmentation of antidepressant therapeutic effects has become more common among geriatric patients, although the risk of drug interactions and potential drug toxicity must be considered. Among substances that have been found useful in younger treatment-resistant patients may be useful in older adults if attention is paid to the need for age-adjusted dosing, the potential for polypharmacy, and behavioral and metabolic drug interactions. More drugs are necessarily better for older depressed patients, but judicious augmenting agents may be helpful. Lithium has recently been shown to have therapeutic augmenting effects, as has thyroid, low-dose stimulants, and atypical antipsychotic agents.

Bipolar Depression

As individuals with bipolar illness age, the pattern of their mood dysregulation commonly shifts from a euphoria/dysphoria oscillation to a mixed picture of both moods and, finally, in old age, primarily a dysphoric mania or treatment-resistant depression. Older patients with a history of bipolar episodes in younger life must be very carefully treated with an antidepressant, usually in conjunction with a mood-stabilizing medication such as lithium or, preferably, an anticonvulsant such as lamotrigine. Monotherapy with an antidepressant frequently causes a switch in mood from depression to a hypomanic mixed, or dysphoric hypomania that may be difficult to treat and medically toxic to the older individual. Therefore, unless there a contravening reasons, any antidepressant given to an older bipolar depressed patient should also receive an adjunctive mood stabilizing medication or an antipsychotic drug. No specific antidepressant is indicated for the treatment of bipolar depression, but lamotrigine is a frequently used mood stabilizer for protection against a mood switch, and there are reports of its therapeutic effects for depression. Lurasidone, asenapine, and aripiprazole have also been reported to be effective in late-life bipolar depression.

Managing the depressed geriatric patient also includes educating the patient and family about the nature of depression as a true illness, emphasizing that it is treatable. Patients and their families need to understand that response to medication may take longer than for younger adults, that treatment adherence is essential, and that adverse effects can be expected but are amenable to supportive countermeasures. Weekly contact during the early phases of short-term treatment is recommended for individualizing treatment, providing encouragement and support, reviewing questions and concerns, and monitoring safety (including suicidal potential). Common errors in practice include underdosing, discontinuing treatment too soon, failure to consider possible drug interactions, and polypharmacy. If a patient has not begun to respond by 6 to 8 weeks, compliance should be re-evaluated, dosage or plasma concentration should be optimized, and referral to a geriatric psychiatrist experienced in treatment resistance should be considered.

Late-life depression is often a chronic illness and tends to recur, especially among those whose first depression develops after the age of 60. One must bring a longitudinal model of depression to treatment. Short-term treatment is intended to induce remission, but incomplete remissions are not unusual and commonly lead to relapse. Recurrences after a longer period of recovery are also common. Studies continue to demonstrate the therapeutic benefits of long-term treatment of depression, and it is recommended, therefore, that treatment continue at least 6 months beyond recovery and for longer periods after a second or third episode. Many older patients have chronic depression that requires indefinite maintenance therapy. Long-term prevention of new episodes is best achieved by maintaining patients on the same dosage of antidepressant medication that was used successfully to treat the acute episode.

Treatment of Bipolar Disorders in Later Life. Bipolar disorders constitute 5% to 10% of the diagnoses of older psychiatric inpatients. The diagnosis of a manic episode is usually not difficult in older individuals, although advanced age is associated with greater degrees of irritability and less euphoria. Most manic older adult patients have a history of prior manic episodes; the onset of a first manic episode in late life is unusual and often is associated with another illness, such as thyroid dysfunction or alcohol or substance abuse. Older individuals who have suffered repeated episodes of mania and depression over the course of their lives are likely to be quite dysfunctional when manic, with rapid shifts of mood. Episodes of euphoria decrease with advanced age and are replaced by “dysphoric” or “mixed” mood states characterized by anger, irritability, paranoid ideation, and depression**.** Diagnostic principles follow the suggestions for evaluation of an older depressed patient, therefore, including a careful and comprehensive medical evaluation, laboratory screening, and history of past or current drug and alcohol use. Older patients with bipolar disorder have a higher body mass index (BMI) and a greater burden of endocrine, metabolic, and respiratory disease.

Despite growing clinical experience in treating older individuals with bipolar disorder, the research and clinical trials literature is less extensive than the geriatric antidepressant literature. In principle, therefore, the management of mania in older patients is similar to that in younger patients, although there may be a relatively poor response to standard pharmacologic treatment in patients with long-standing bipolar illness. Treatment of the acute manic episode is focused on two separate categories of dysfunction: (1) management of manic behavior and impaired sleep, and (2) regulation of excessive or inappropriate mood states. Agitated, hyperactive older manic patients or those who are psychotic, as well as patients with impaired sleep, may be helped by treatment with antipsychotic drugs. All antipsychotics are effective for these symptoms, although current practice favors the use of second-generation drugs in order to avoid excessive extrapyramidal symptoms caused by conventional neuroleptics. Risperidone, olanzapine, and quetiapine are commonly used for this purpose; clozapine is also therapeutic, but its use in older patients is associated with numerous potentially serious side effects; other medications (e.g., ziprasidone, aripiprazole, lurasidone, olanzapine asenapine) may also be helpful, but research studies in older adults of any of these medications are scant and do not provide adequate prescribing information. In general, therefore, starting doses of an atypical antipsychotic drug should be low, with gradual dose increases; clinicians should resist the pressure to rapidly increase doses to control behavioral disruption. When an atypical neuroleptic is given at bedtime, sleep is often promoted, which, in turn, may help diminish the manic symptoms.

Lithium

Regulation of mood is accomplished by the use of mood-stabilizing medications; principles of their use follow guidelines for younger adults, although older individuals are significantly more sensitive to side effects. Lithium, for example, commonly produces side effects at doses and blood levels that are not toxic in younger people. For example, delirium can develop at lithium concentrations at or even below the young adult therapeutic lithium plasma concentration range. Delirium and cerebellar dysfunction may last for weeks after discontinuation of lithium use. Lithium-induced tremor is more frequent in older patients than in younger patients. Lithium can worsen Parkinson disease or produce parkinsonism in neurologically intact older patients and can also worsen cognitive function, especially in demented patients. Sinoatrial block can be caused by lithium, a risk that is increased by the concurrent use of digitalis and β-adrenergic receptor antagonists (β-blockers). Older patients often receive drugs that increase lithium plasma concentrations, including thiazide diuretics, nonsteroidal anti-inflammatory drugs, or angiotensin-converting enzyme inhibitors. Age-induced decrements in glomerular filtration rates and renal blood flow reduce lithium excretion, and a decline in glomerular filtration rate may accompany long-term lithium use. Because of the potential for toxicity and impairment of renal function, lithium use should be restricted to selected older patients whose physical health and ability to comply with prescribing guidelines and laboratory studies are evident. Starting dosages of 75 to 150 mg a day may reduce adverse effects and improve compliance. These very low doses may successfully treat the disturbed mood with lower, nontoxic blood levels than in younger adults (e.g., 0.2 to 0.4 mM/L). Chronic lithium treatment may also adversely affect thyroid function leading to a hypothyroid state that may resemble depression or aggravate pre-existing depression. It is essential, therefore, that lithium use in older adults be accompanied by regular checks of renal and thyroid function.

Anticonvulsant Mood Stabilizers

It is now well established that some anticonvulsant medications also are excellent mood stabilizers and may be effective and safe for older individuals. Like lithium, however, anticonvulsants are used primarily to prevent the recurrence of dysregulated mood states. For example, the anticonvulsants carbamazepine (Tegretol) and divalproex sodium

(Depakote) have demonstrated prophylactic effectiveness in older individuals. However, these two anticonvulsants affect cytochrome P450 metabolizing enzymes and may affect blood levels of other medications given for psychiatric or medical conditions. Carbamazepine induces enzyme metabolism, while Depakote inhibits metabolism. Current prescribing practice favors the use of lamotrigine (Lamictal) as a stabilizing anticonvulsant for older adults. Although a few individuals may develop a skin rash with this drug (less likely in older adults), the side-effect profile is benign, and with low therapeutic doses (12.5 to 100.0 mg/day), there may be few or no side effects. Oxcarbazepine (Trileptal) is also sometimes used to stabilize mood in younger adults, but there are no studies of its effectiveness in older adults.

Most anticonvulsants are metabolized by hepatic metabolizing enzymes, primarily CYP 3A4. Hematologic and liver function tests are needed prior to treatment with anticonvulsants to ensure their safe use. Carbamazepine induces its own metabolism, so blood levels may need to be adjusted during treatment. This drug can also cause leukopenia (white blood cell counts below 4,000 /mm) in approximately 2% of cases; it should not be used for routine geriatric patient treatment. Valproate inhibits the CYP450 3A4 metabolizing enzyme and can cause elevations of other medications that use this metabolic pathway (e.g., lamotrigine, some benzodiazepines, and antidepressants). Valproate can also cause increased ammonia levels and toxic neurologic states, although it is not clear that older individuals are more susceptible to this side effect. Lamotrigine, currently the preferred mood-stabilizing anticonvulsant for older adults, is metabolized by CYP450 3A4, and its blood levels can be affected by other medications (e.g., valproate, fluoxetine) that inhibit this enzyme. Oxcarbazepine can cause a sudden decrease in serum sodium, followed by a change in mental status that may be mistaken for a worsening psychiatric condition. Levetiracetam has been used as a mood stabilizer in a small number of older patients. Other new anticonvulsants have not been tried on older adults and cannot be recommended.

Prescribing guidelines for lithium and anticonvulsant treatment of late-life mood dysregulation follow the general geriatric prescribing principle: “start low and go slow.”

Continuation and maintenance treatment is necessary for older bipolar patients who achieve remission of a manic or depressive episode. Although studies of geriatric populations are lacking, studies of younger patients suggest that lithium, carbamazepine, and valproate are effective in preventing both depressive and manic episodes. For this reason, continuation and maintenance of treatment with these drugs should be considered for older patients. Older patients, in particular, should be carefully and frequently monitored for alterations in medical conditions, especially hepatic function, as well as cognitive function. As the older bipolar patient continues to age, dosage modifications are likely to be necessary.

55.4c Antianxiety Drugs

ALASTAIR J. FLINT, M.B., AND KATHLEEN S. BINGHAM, M.D., PH.D.

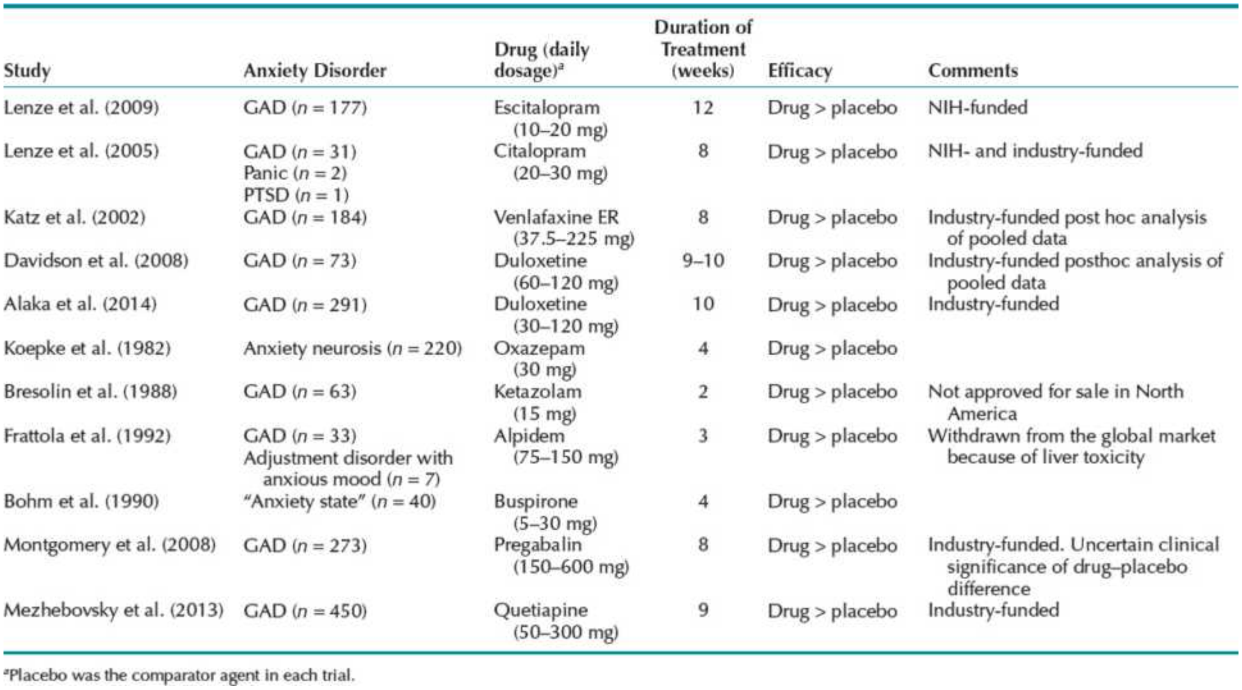
Anxiety disorders are common in late life, with 5% to 10% of community-dwelling older adults meeting the criteria for a current anxiety disorder. Despite this prevalence, there has been relatively little research on the pharmacologic treatment of anxiety in older adults, and most treatment decisions in this group need to rely on research conducted in younger adults. Extrapolating findings from younger to older adults is, however, potentially problematic, given the pharmacokinetic and pharmacodynamic changes that occur with aging. In particular, the efficacy, tolerability, and safety of drugs in older adults can be affected by age-related physiologic changes (such as the increased volume of distribution of lipophilic drugs, decreased function of the liver and kidneys, and changes in organ receptor sensitivity), the increased frequency of comorbid medical and neurologic conditions, and the fact that older adults take more medications than their younger counterparts, thereby increasing the risk of drug–drug and drug–body interactions. This chapter will highlight issues that are of particular relevance to older adults in the pharmacologic treatment of anxiety.

Double-blind, randomized controlled trials (RCTs) are the gold standard for evaluating treatment efficacy. Nonblind ("open-label") and uncontrolled studies are of limited use in guiding treatment because of the significant biases and confounds that can affect their findings. There have been 11 double-blind RCTs of the pharmacologic treatment of anxiety disorders in persons aged 60 years or older (Table 55.4c–1), but only nine studies pertain to drugs approved for sale in North America. Nine of the 11 RCTs focused on generalized anxiety disorder (GAD), while two studies included participants with nonspecific anxiety.

Given that the diagnostic category of anxiety disorders has traditionally included phobic disorders, panic disorder, GAD, post-traumatic stress disorder (PTSD), and obsessive-compulsive disorder (OCD), why have treatment studies in the elderly focused almost exclusively on GAD? Knowledge of the epidemiology of anxiety disorders in later life helps answer this question. First, phobias and GAD are the most prevalent anxiety disorders in older adults. However, the most common presentations of phobia in later life, that is, agoraphobia without panic and specific phobia, tend not to come to psychiatric attention. In addition, the treatment of choice for these two disorders is behavioral therapy, not pharmacotherapy. Therefore, GAD is the most frequently occurring late-life anxiety disorder in psychiatric practice that is medication-responsive. Second, panic disorder, OCD, and social anxiety disorder (social phobia) have a low incidence and prevalence in later life, and therefore clinicians and researchers may view them as less compelling to study compared with disorders with a higher incidence and prevalence. In contrast, approximately half of the cases of syndromal generalized anxiety in older adults are late onset, often in association with major depression. Finally, syndromal and subsyndromal generalized anxiety is the most common manifestation of anxiety associated with medical illness and cognitive impairment in older persons, again frequently in association with depression.

The 11 RCTs in Table 55.4c–1 have evaluated the efficacy and tolerability of antidepressants, benzodiazepines, nonbenzodiazepine anxiolytics, an anticonvulsant, and an atypical antipsychotic in the treatment of late-life GAD. The remainder of this chapter will discuss these classes of drugs, as well as comment on miscellaneous drugs that have been examined in younger persons with anxiety.

Table 55.4c–1.
All Published Double-Blind Randomized Controlled Trials of the Pharmacologic Treatment of Anxiety Disorders in Persons Aged 60 Years or Older (Circa 2022)



Study	Anxiety Disorder	Drug (daily dosage)[a]	Duration of Treatment (weeks)	Efficacy	Comments
Lenze et al. (2009)	GAD (*n* = 177)	Escitalopram (10–20 mg)	12	Drug > placebo	NIH-funded
Lenze et al. (2005)	GAD (*n* = 31) Panic (*n* = 2) PTSD (*n* = 1)	Citalopram (20–30 mg)	8	Drug > placebo	NIH- and industry-funded
Katz et al. (2002)	GAD (*n* = 184)	Venlafaxine ER (37.5–225 mg)	8	Drug > placebo	Industry-funded post hoc analysis of pooled data
Davidson et al. (2008)	GAD (*n* = 73)	Duloxetine (60–120 mg)	9–10	Drug > placebo	Industry-funded posthoc analysis of pooled data
Alaka et al. (2014)	GAD (*n* = 291)	Duloxetine (30–120 mg)	10	Drug > placebo	Industry-funded
Koepke et al. (1982)	Anxiety neurosis (*n* = 220)	Oxazepam (30 mg)	4	Drug > placebo	
Bresolin et al. (1988)	GAD (*n* = 63)	Ketazolam (15 mg)	2	Drug > placebo	Not approved for sale in North America
Frattola et al. (1992)	GAD (*n* = 33) Adjustment disorder with anxious mood (*n* = 7)	Alpidem (75–150 mg)	3	Drug > placebo	Withdrawn from the global market because of liver toxicity
Bohm et al. (1990)	"Anxiety state" (*n* = 40)	Buspirone (5–30 mg)	4	Drug > placebo	
Montgomery et al. (2008)	GAD (*n* = 273)	Pregabalin (150–600 mg)	8	Drug > placebo	Industry-funded. Uncertain clinical significance of drug–placebo difference
Mezhebovsky et al. (2013)	GAD (*n* = 450)	Quetiapine (50–300 mg)	9	Drug > placebo	Industry-funded

[a] Placebo was the comparator agent in each trial.

ANTIDEPRESSANTS

In recent years, there has been growing awareness that antidepressant medications have a broad spectrum of efficacy in the treatment of anxiety disorders in younger adults. RCTs in mixed-age patients have found that antidepressants of various classes are beneficial in the treatment of GAD, panic disorder, social anxiety disorder, PTSD, and OCD (Table 55.4c–2).

RCTs of antidepressant pharmacotherapy in older people with an anxiety disorder found that escitalopram (Lexapro), citalopram (Celexa), and Duloxetine (Cymbalta) are more efficacious than placebo in treating GAD (Table 55.4c–1). In addition, a post hoc analysis of data pooled from RCTs found that venlafaxine (Effexor) had greater efficacy than placebo in older persons with GAD. In the escitalopram, citalopram, and venlafaxine studies, approximately two-thirds of participants treated with the drug were classified as responders after 8 to 12 weeks of treatment, compared with placebo response rates of 24% for citalopram, 41% for venlafaxine, and 51% for escitalopram. In the duloxetine clinical trial, the 10-week rate of response was 71.3% for duloxetine and 45.5% for placebo. Thus, there is a high rate of placebo response in clinical trials of later-life GAD, highlighting the importance of nonpharmacologic factors contributing to symptomatic improvement in these studies. The venlafaxine analysis also compared response rates between younger and older participants and found almost identical rates of response to drug and placebo between the two age groups. Compared to placebo, statistically significant adverse events were: fatigue/somnolence, sleep disturbance, and urinary symptoms with escitalopram; gastrointestinal symptoms with venlafaxine; and dry mouth, nausea, and weight loss with duloxetine. There was no significant difference in adverse effects between citalopram and placebo. However, the analysis was limited by the small number of participants in that study.

Table 55.4c–2.
Drugs Found Efficacious in Randomized Controlled Trials Treating Anxiety Disorders in Mixed-Age Samples

Disorder	Drug
Generalized anxiety disorder (GAD)	SSRI: escitalopram[a], fluoxetine, paroxetine[a] SNRI: duloxetine[a], venlafaxine[a] TCA: imipramine Other Antidepressants: trazodone Benzodiazepine: various Azapirone: buspirone[a] Other: hydroxyzine, pregabalin, quetiapine
Panic disorder with or without agoraphobia	SSRI: citalopram, fluoxetine[a], fluvoxamine, paroxetine[a], sertraline[a] SNRI: venlafaxine[a] TCA: clomipramine, desipramine, imipramine MAOI: brofaromine, phenelzine Benzodiazepine: alprazolam[a], clonazepam[a], diazepam, lorazepam
Social anxiety disorder	SSRI: fluvoxamine, paroxetine[a], sertraline[a] SNRI: venlafaxine[a] MAOI: brofaromine, moclobemide, phenelzine Benzodiazepine: alprazolam, clonazepam
Post-traumatic stress disorder (PTSD)	SSRI: fluoxetine, paroxetine[a], sertraline[a] SNRI: venlafaxine TCA: amitriptyline, imipramine MAOI: phenelzine Other: prazosin (nightmares)
Obsessive-compulsive disorder	SSRI: fluoxetine[a], fluvoxamine[a], paroxetine[a], sertraline[a] TCA: clomipramine[a]

[a] FDA-approved.

SSRI, selective serotonin reuptake inhibitor; SNRI, serotonin and norepinephrine reuptake inhibitor; TCA, tricyclic antidepressant; MAOI, monoamine oxidase inhibitor.

Selective Serotonin Reuptake Inhibitors

Of the selective serotonin reuptake inhibitors (SSRIs), escitalopram and citalopram are well suited to older persons. They have linear pharmacokinetics across the dose range (that is, an increase in dose results in a predictable increase in plasma concentration), no clinically active metabolites, elimination half-lives of 33 hours or less, and little propensity for drug–drug interactions. In addition, sertraline (Zoloft) is also suitable in older persons because of its favorable pharmacokinetic profile. Although data from RCTs in mixed-age patients have demonstrated the efficacy of sertraline in several anxiety disorders (Table 55.4c–2), there are no controlled data pertaining to sertraline in late-life anxiety disorders, although it has been found to be efficacious, safe, and well-tolerated in late-life depression. On the other hand, paroxetine and fluoxetine have less favorable pharmacokinetic profiles in older adults, and paroxetine has the potential to cause anticholinergic adverse effects such as worsening cognitive function, blurred vision, dry mouth, constipation, and urinary hesitancy; therefore, these drugs are not recommended as first-line SSRIs in older adults.

If started at too high a dose, SSRIs may initially exacerbate symptoms of anxiety and, therefore, a lower starting dose (for example, 2.5 mg/day of escitalopram, 5 mg/day of citalopram, or 25 to 50 mg of sertraline) is often indicated in older adult anxious individuals. Once it has been established that the patient is tolerating the starting dose, the dose should then be gradually increased to the usual therapeutic range (Table 55.4c–3). Both citalopram and escitalopram have been associated with dose-dependent prolongation of the QTc interval on EKG and, as a result, it is recommended not to exceed 20 mg/day of citalopram in persons aged 60 years or older and 10 mg/day of escitalopram in persons 65 years or older. Anxious patients frequently misattribute somatic symptoms of anxiety to the adverse effects of medication. Thus, in addition to starting with a low dose of antidepressant, adherence to medication can be enhanced by discussing potential side effects in advance, frequent monitoring of the patient during the first few weeks of treatment, and availability of the clinician by telephone between appointments to address any questions or concerns that the patient may have about treatment.

Based on the above considerations, escitalopram is a reasonable first-line choice for the treatment of GAD in later life, given that it has FDA approval for this condition and there are efficacy and tolerability data specific to older adults. In the absence of pharmacotherapy data pertaining to anxiety disorders other than GAD in older adults, sertraline would be a reasonable first-line SSRI for panic, social anxiety, PTSD, and OCD, given that it has FDA approval for the treatment of these disorders based on studies of mixed-age samples, it has a favorable pharmacokinetic and tolerability profile in older patients, and there is considerable flexibility in dosing without the concern of QTc prolongation at higher doses.

Table 55.4c–3.
Usual Starting Dose, Initial Target Dose, and Recommended Maximum Dose of Selected SSRIs and SNRIs in Older Adults with Anxiety Disorders

Drug	Usual Starting Dose (mg/day)	Initial Target Dose (mg/day)	Recommended Maximum Dose (mg/day)
Escitalopram	2.5	5	10
Citalopram	5	10	20
Sertraline	25	50–100	200
Venlafaxine ER	37.5	150	300
Duloxetine	30	60	120

SSRI, selective serotonin inhibitor; SNRI, serotonin and norepinephrine reuptake inhibitor.

Serotonin and Norepinephrine Reuptake Inhibitors

Venlafaxine is a serotonin and norepinephrine reuptake inhibitor (SNRI), although it has been postulated that its noradrenergic effect occurs only at higher doses (possibly 150 mg/day or higher). The doses used to treat GAD in older persons in RCTs were relatively low (75 to 150 mg/day in the majority of older subjects), raising the possibility that the serotonergic action of the drug may be sufficient to treat GAD in many older patients. Like escitalopram, citalopram, and sertraline, venlafaxine has linear pharmacokinetics and lacks a propensity for significant drug–drug interactions. The usual starting dose of venlafaxine ER in older persons is 37.5 mg/day, with dose increments of 37.5 mg every 4 to 5 days to reach a minimum target dose of 150 mg/day. The dose range of venlafaxine ER is wide (75 to 375 mg/day), and the usual therapeutic dose for GAD has not been established in older patients. However, if there has not been a satisfactory improvement of GAD after 4 weeks of treatment at a dose of 150 mg/day, the dose should be gradually increased, guided by response and tolerability (Table 55.4c–3). Venlafaxine is a suitable antidepressant for older persons with GAD, and on the basis of RCTs conducted in mixed-age samples, it can also be considered as a first-line option for panic, social anxiety, and PTSD. Given that Venlafaxine and SSRIs are different drug classes, switching from one class to the other (i.e., from an SSRI to venlafaxine or vice versa) is a reasonable approach in the case of inadequate response to a therapeutic trial of the first drug.

Duloxetine has a more circumscribed role in the treatment of anxiety since it is indicated only in the treatment of GAD (Table 55.4c–2). Duloxetine has linear pharmacokinetics across a dose range of 30 to 120 mg/day. In older adults, a starting dose of 30 mg/day is recommended, increasing to an initial target dose of 60 mg/day if tolerated. If there has been insufficient improvement after 4 weeks, the dose can be gradually increased by 30 mg increments to a maximum of 120 mg/day, guided by response and tolerability. Duloxetine is both an inhibitor and substrate of cytochrome P450 2D6 (CYP2D6) and thus has the potential for interaction with other drugs metabolized by this enzyme. Given that CYP2D6 catalyzes the metabolism of a large number of drugs, this unwanted property of duloxetine should be taken into account when deciding on the choice of an SNRI to treat late-life GAD.

Other Antidepressants

In addition to SSRIs and SNRIs, selected tricyclic antidepressants (TCAs) and monoamine oxidase inhibitors (MAOIs) have been found to be efficacious in a range of anxiety disorders in younger adults (Table 55.4c–2), although there have been no comparable studies in older adults. With the exception of desipramine (Norpramin), the TCAs that have been examined in younger persons have been tertiary amine compounds, which are potentially problematic in older adults. In particular, older adults may be vulnerable to the anticholinergic, sedative, hypotensive, and adverse cardiac effects of tertiary amine TCAs, especially if they have concomitant physical or cognitive problems that could be aggravated by these effects. A post hoc analysis of data pooled from three RCTs of the treatment of poststroke depression found that nortriptyline (Aventyl) (a secondary amine TCA that is preferred over tertiary amine TCAs in older adults) was more effective than placebo in treating generalized anxiety associated with the depression. Thus, if a TCA is considered for an older anxious person, the recommendations would be desipramine in the case of panic disorder and either nortriptyline or desipramine (which is a metabolite of imipramine [Tofranil]) in the case of GAD. Although OCD rarely starts as a primary disorder in later life, older persons with chronic OCD may present for treatment. Clomipramine (Anafranil), a serotonergic tertiary amine TCA, can be a useful treatment for OCD, especially in cases that have failed to adequately improve with SSRIs. While the use of clomipramine has potential limitations in older adults because of its side-effect profile, it is worth considering, in combination with cognitive behavior therapy, in selected older persons who have OCD and that has failed to respond to other medications. Similarly, first-generation MAOIs such as tranylcypromine (Parnate) or phenelzine (Nardil) should be kept in mind as a potential treatment for refractory panic disorder, social phobia, or PTSD, or for refractory anxious depression. However, the need to avoid tyramine-containing foods and certain medications to prevent the development of a hypertensive crisis, and the potential for these drugs to cause significant supine and orthostatic hypotension (as well as weight gain associated with phenelzine), will limit the use of MAOIs to carefully selected individuals.

Vortioxetine (Brintellix) is a serotonergic antidepressant that differs from SSRIs in neurochemical activity in that it modulates a variety of serotonin receptors in addition to inhibiting the reuptake of serotonin. A recent meta-analysis of four RCTs found no difference between vortioxetine and placebo in rates of response and remission of GAD in mixed-age adults. To our knowledge, vortioxetine has not been studied in RCTs as a treatment for other anxiety disorders.

BENZODIAZEPINES

Despite their widespread use, benzodiazepines have a limited role in the treatment of late-life anxiety. First, they are not a useful treatment for two of the three most common anxiety disorders in later life, that is, specific phobias and agoraphobia without panic. Second, the frequent comorbidity of GAD with depression in later life suggests the need for medication with both antidepressant and anxiolytic effects. Benzodiazepines are not an effective treatment for the core symptoms of depression. On the other hand, antidepressant medication is an effective treatment for GAD even when depression is absent. Third, there are a number of risks associated with benzodiazepines in older adults, including cognitive impairment, psychomotor impairment, excessive daytime sedation, instability of gait, falls, and hip fractures. Finally, anxiety disorders tend to be chronic conditions, with most patients requiring long-term treatment. Long-term use of benzodiazepines can be associated with psychological and physical dependence and tolerance, so it can be difficult to discontinue the drug if its benefits diminish and/or adverse effects develop. Persons with a history of alcoholism or drug abuse may be at particular risk of becoming dependent on a benzodiazepine.

In situations where benzodiazepines are indicated (for example, acute situational anxiety or as a short-term adjunct to an antidepressant until the antidepressant becomes effective), lorazepam (Ativan) or oxazepam (Serax) are preferred in older adults because they have relatively short elimination half-lives (10 to 15 hours), no active metabolites, and they do not undergo oxidative metabolism in the liver (thus, their clearance is not affected by age). As a result, these drugs do not have the potential for cumulative toxicity in older adults, which is a risk associated with longer-acting compounds such as diazepam or clonazepam. Oxazepam is slowly absorbed, so it is not very effective as a hypnotic unless it is taken at least an hour before bedtime. The usual dosage range in older adults is lorazepam 0.5 to 1.5 mg/day and oxazepam 10 to 30 mg/day. Although alprazolam (Xanax) is FDA-approved for the treatment of GAD and panic disorder, there are no data pertaining to its risk-benefit profile in older persons with these conditions. Alprazolam has a high potential for dependence and abuse. Its relatively short elimination half-life can result in rebound anxiety, which can lead to patients taking more frequent doses and higher daily doses than prescribed. For these reasons, alprazolam is not recommended for older adults.

As noted, most older adults who are prescribed a benzodiazepine do not require the drug on an ongoing basis. However, there are occasions when long-term benzodiazepine treatment may be necessary. In particular, some patients who have been maintained on a benzodiazepine for years experience a significant worsening of anxiety when an attempt is made to withdraw the medication. In such cases, if the benzodiazepine is not causing significant side effects, it is usually the least disruptive to leave the individual on the medication and monitor them on a regular basis. If side effects do become an issue as the person grows older, dose reduction rather than complete discontinuation of the drug may be the best compromise. In addition, some patients do not experience adequate relief of anxiety symptoms with a nonbenzodiazepine medication alone, and in these cases, longer-term treatment with an adjunctive benzodiazepine, given at the lowest possible dose, may be necessary.

BUSPIRONE

Buspirone (Buspar), an azapirone derivative and a serotonin-1A receptor partial agonist, is a nonbenzodiazepine anxiolytic that is more efficacious than a placebo in the treatment of GAD. It is not indicated in the treatment of other anxiety disorders. Although buspirone and benzodiazepines have comparable efficacy in patients with GAD who persist with treatment, several studies have found that patients are more likely to discontinue buspirone than a benzodiazepine for reasons other than side effects. It has been suggested that the higher rate of discontinuation of buspirone compared with a benzodiazepine may be due to buspirone’s delayed onset of action.

Although buspirone is an efficacious treatment for GAD, it has a limited role in the treatment of generalized anxiety in late life. First, it is not a substitute for antidepressant medication in the treatment of generalized anxiety that is comorbid with, or secondary to, major depression. Second, because buspirone has a delayed onset of action, it is not suitable as an acute adjunctive treatment for generalized anxiety symptoms associated with major depression. Third, there is evidence that buspirone may have diminished efficacy in persons who have previously been treated with a benzodiazepine. Therefore, its usefulness in the management of older adult patients with chronic GAD, many of whom have been treated with benzodiazepines, is unclear. Finally, the twice-a-day to three-times-a-day dosing schedule of buspirone increases the risk of poor adherence to this medication.

Unlike benzodiazepines, buspirone does not cause sedation, psychomotor impairment, cognitive impairment, or depressed respiratory drive. This side-effect profile suggests that it would be preferable to a benzodiazepine in the ongoing management of generalized anxiety in nondepressed patients who have chronic obstructive airway disease, sleep apnea, or a neurologic disorder. However, select antidepressants may also be effective for anxiety and well tolerated in these patients.

The usual starting dose of buspirone in older patients is 5 mg twice a day, followed by dose increments of 5 mg every 4 to 5 days to reach a target dose of 20 to 30 mg/day, given in divided doses. If a person fails to show significant improvement after 4 to 6 weeks at this target dose, the dose can be further gradually increased to a maximum of 45 mg/day, as tolerated. The main side effects of buspirone are dizziness, headache, and nausea. Gradual dose titration is essential in order to minimize the risk of these effects.

Sometimes a physician elects to switch a patient from long-term benzodiazepine therapy to buspirone. Because buspirone has a delayed onset of action and does not suppress benzodiazepine withdrawal symptoms, a patient should not be abruptly switched from a benzodiazepine to buspirone. Instead, the patient should take a therapeutic dose of buspirone for 2 to 4 weeks before the benzodiazepine is gradually tapered. Despite this approach, some patients are less satisfied with the anxiolytic effect of buspirone compared with that of a benzodiazepine.

OTHER DRUGS

Pregabalin

Pregabalin (Lyrica) is an anticonvulsant drug that binds to the alpha-2-delta subunit of the voltage-dependent calcium channel in the central nervous system and decreases the release of neurotransmitters, including glutamate, norepinephrine, and substance P. Unlike benzodiazepines, pregabalin does not bind to gamma-aminobutyric acid (GABA) receptors and does not alter GABA metabolism. Several industry-funded RCTs in mixed-age patients have found that pregabalin is more efficacious than a placebo in the treatment of GAD, although pregabalin does not have FDA approval for this indication. Although a statistically significant difference between 150 to 600 mg/day of pregabalin and placebo was found in patients aged 65 years or older with GAD, the clinical significance of the difference is uncertain: there was only a 2-point greater reduction in HAM-A scores with drug versus placebo (12.9 vs.

10.7). Moreover, pregabalin and placebo groups did not differ in response or remission rates at the end of the 8-week study. Pregabalin was well tolerated in this group of older patients.

Quetiapine XR

First-generation antipsychotic medications have long been used in the acute treatment of agitation, but they are not recommended as a treatment for primary anxiety disorders because of the risk of tardive dyskinesia associated with their longer-term use. Quetiapine XR (Seroquel XR) is a second-generation atypical antipsychotic with a low risk of neurologic side effects. An industry-funded study found that 50 to 300 mg/day of quetiapine XR was more efficacious than placebo in treating GAD in older adults, with significant differences in response and remission rates by the end of 8 weeks of treatment. While quetiapine has a low risk of parkinsonism and tardive dyskinesia, and it can be associated with weight gain and metabolic dysfunction and, as a result, cannot be recommended as a routine first-line treatment of GAD in older adults.

Beta Blockers and Antihistamines

Beta blockers (e.g., 10 to 20 mg of propranolol [Inderal]) can be effective for performance anxiety when given about one hour prior to the feared performance. Therefore, they can be useful in patients with specific types of social anxiety disorder, such as public speaking or eating in public. However, beta-blockers should be avoided in anxious patients with sinus bradycardia, hypotension, or asthma.

RCTs conducted in Europe have found that the antihistamine drug hydroxyzine (Atarax) is more efficacious than a placebo and comparable in efficacy to a benzodiazepine and buspirone in the treatment of GAD in mixed-age adults. Hydroxyzine has not been studied as a treatment of GAD in late life, but its sedative and anticholinergic effects (increasing the risk of daytime somnolence, cognitive impairment, and falls and fractures) limit its usefulness in older patients.

55.4d Antipsychotic Drugs

KELLY C. LEE, PHARM.D., M.A.S., B.C.P.P., AND VIVIAN HOOK, PH.D.

Antipsychotic medications constitute the treatment of choice for psychoses associated with schizophrenia or schizoaffective disorder. Antipsychotics are frequently prescribed for older adults in the treatment of psychosis and severe behavioral disturbances such as agitation and aggression. Although nonpharmacologic therapies may be helpful in milder states of behavioral disturbances associated with cognitive disorders such as dementia, antipsychotics are often necessary to treat severe symptoms. Age-related physiologic changes in older adults can increase sensitivity to adverse events from these medications. Treatment is also often complicated by the frequent presence of comorbid medical conditions and medication interactions in older adults. Despite the complexities, antipsychotic medications are commonly prescribed to older patients in inpatient, outpatient, residential, and nursing home settings.

Antipsychotics are broadly classified into two groups. The older agents (i.e., introduced in the United States before 1990) are referred to as first generation and primarily block dopamine receptors (primarily D2) to exert antipsychotic effects. First generation antipsychotics (FGAs), while effective for positive symptoms of schizophrenia, are associated with undesirable extrapyramidal symptoms and endocrine changes.

Second generation antipsychotics (SGA) have an absence or decreased incidence of extrapyramidal effects and tardive dyskinesia, as well as an expanded spectrum of activity against negative symptoms associated with schizophrenia. Because of their improved neurologic profile, SGAs have generally replaced FGAs. Unfortunately, due to studies that ultimately led to black box warning labeling for antipsychotics when used in older adult patients with dementia, the benefits of using these agents must be carefully weighed against the potential risks.

PHARMACOLOGIC ACTIONS

Pharmacokinetics and Pharmacodynamics

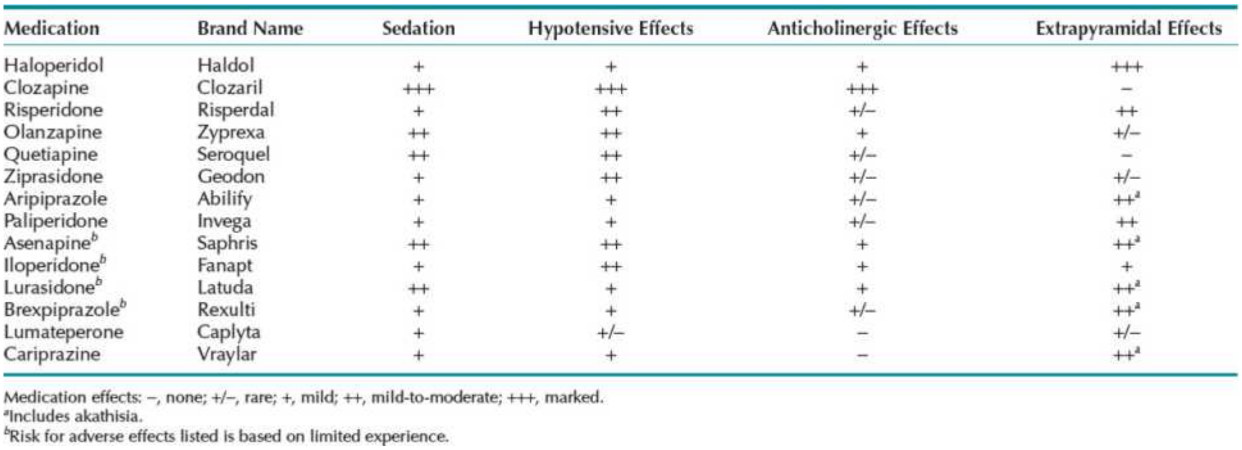
Pharmacokinetics can generally be described as the body's effect on the absorption, distribution, metabolism, and elimination of drugs. Numerous age-related changes in physiology may affect pharmacokinetics. Changes in pharmacodynamics (the drug's effect on the body) are also likely to occur; however, these mechanisms are not as well understood relative to the knowledge of age-related pharmacokinetic changes. Neurotransmitter and receptor function changes in the central nervous system may increase sensitivity to drugs, and toxicity may occur at lower plasma levels. In general, these pharmacokinetic and pharmacodynamic changes may lead to higher blood levels of medications, prolonged pharmacologic effects, and a greater risk for side effects in older adults.

Receptor Activity

The specific mechanism of action of antipsychotics has not been elucidated, but most of the research attention has focused on the receptor blockade of dopamine and serotonin. While the FGAs have been shown to work through the blockade of the central dopamine receptors (specifically D2), SGAs have been referred to as serotonin–

dopamine antagonists as they block both 5-HT$_{2A}$ and D2 receptors. Antipsychotic drugs also affect other receptors, usually resulting in adverse effects rather than an enhanced therapeutic response. For example, histamine-1 (H$_1$) blockade is responsible for sedation and possibly weight gain. Blockade of the 5-HT$_{2C}$ receptor may also play a role in weight gain associated with some SGAs. Blockade of the α$_1$ receptors causes orthostatic hypotension, whereas α$_2$ blockade plays a role in sexual dysfunction. Muscarinic receptor blockade results in classical anticholinergic effects such as dry mouth, blurred vision, constipation, and urinary retention. An understanding of the receptor-binding properties of the FGAs and SGAs can predict their adverse effect profiles (Table 55.4d–1).

Table 55.4d–1.
Relative Adverse Effects for Selected Antipsychotics



Medication	Brand Name	Sedation	Hypotensive Effects	Anticholinergic Effects	Extrapyramidal Effects
Haloperidol	Haldol	+	+	+	+++
Clozapine	Clozaril	+++	+++	+++	–
Risperidone	Risperdal	+	++	+/–	++
Olanzapine	Zyprexa	++	++	+	+/–
Quetiapine	Seroquel	++	++	+/–	–
Ziprasidone	Geodon	+	++	+/–	+/–
Aripiprazole	Abilify	+	+	+/–	++[a]
Paliperidone	Invega	+	+	+/–	++
Asenapine[b]	Saphris	++	++	+	++[a]
Iloperidone[b]	Fanapt	+	++	+	+
Lurasidone[b]	Latuda	++	+	+	++[a]
Brexpiprazole[b]	Rexulti	+	+	+/–	++[a]
Lumateperone	Caplyta	+	+/–	–	+/–
Cariprazine	Vraylar	+	+	–	++[a]

Medication effects: –, none; +/–, rare; +, mild; ++, mild-to-moderate; +++, marked.

[a] Includes akathisia.

[b] Risk for adverse effects listed is based on limited experience.

THERAPEUTIC INDICATIONS FOR ANTIPSYCHOTICS

Early-Onset Schizophrenia

Historically, it has been thought that all patients with schizophrenia uniformly follow a poor prognostic course with no return to a premorbid level of functioning. Fortunately, long-term studies in chronic schizophrenia have been more optimistic. Approximately one-third of patients either undergo remission or have only mild symptoms over the long term, while 15% to 20% of patients get worse. The remaining patients appear to have a stable course. Patients who have benefited from maintenance antipsychotic treatment with prolonged absence of psychotic symptoms may warrant a trial of medication. Older patients typically have fewer and less severe positive symptoms than younger patients, while negative symptoms tend to persist into late life. Relapse and exacerbation may occur in older patients with chronic schizophrenia just as they do in younger patients, and investigators have struggled to identify factors that may predict an outcome. Hence, if a drug withdrawal is attempted, careful monitoring is required.

Late-Onset Schizophrenia

Approximately 20% to 30% of patients have onset of symptoms after 40 years of age and are considered to have late-onset schizophrenia (LOS). In general, regardless of the age of onset of schizophrenia (LOS vs. early-onset schizophrenia [EOS]), patients with schizophrenia are similar in terms of positive symptoms, such as delusions and hallucinations, chronicity of the course of illness, and family history. However, LOS seems to be more common in women, and those with LOS have better premorbid functioning with successful occupations and marital histories, fewer negative symptoms, and less severe neurocognitive impairment. Additionally, patients with LOS typically require lower antipsychotic doses and have fewer positive symptoms compared with EOS patients. Onset after age 65 usually signifies very LOS-like psychosis, which is typically secondary to general medical conditions such as dementia or neurodegenerative disorder. Additional studies are needed to identify genetic variants, biomarkers, and changes in neuroimaging studies that may differentiate LOS from EOS.

Delusional Disorder

Delusional disorder refers to the presence of one or more persistent, nonbizarre delusions and may be misdiagnosed as schizophrenia. Delusions commonly involve situations that may occur in real life, such as being poisoned, having a disease, or experiencing spousal infidelity. Delusional disorder generally presents in middle or late life and can be differentiated from schizophrenia by the absence of prominent auditory or visual hallucinations and by the lack of functional deterioration outside the area of delusions. Psychiatric comorbidities, especially depressive disorders, are common among those with delusional disorders. Mild symptoms may be treated without medications, but antipsychotics may be helpful for the agitated patient whose delusions have a negative impact on social relationships or functional behaviors. Antipsychotic nonadherence is a common problem in those with delusional disorders, although some suggest that women may be more adherent to pharmacologic treatments than men.

Dementia With Psychosis or Severe Behavioral Disturbances

The most common types of dementia are Alzheimer and vascular types. Patients who develop dementias have cognitive impairment resulting in memory and executive functioning decline but also noncognitive dysfunction that can be more distressful. Many older adult patients with dementia develop behavioral disturbances such as aggression, agitation, delusions, and other neuropsychiatric symptoms during their course of illness. These changes in mood, affect, and behavior can lead to early institutionalization, increased caregiver burden, and increased healthcare costs. When behavioral problems arise, early recognition and prompt treatment can improve the quality of life of patients, their families, and caregivers and reduce healthcare costs. In addition to medications used for cognitive dysfunction, nonpharmacologic interventions and antipsychotics have been widely used for treating behavioral disturbances associated with dementia. Treatment guidelines have generally recommended careful assessment, diagnosis, and nonpharmacologic treatment approaches, such as psychosocial and environmental interventions, prior to pharmacologic approaches. When nonpharmacologic approaches fail, the provider, together with the patient and their family, should examine pharmacologic options carefully when severe agitation and psychosis symptoms are dangerous and/or cause significant distress to the patient. The family should be informed about the relative risks and benefits of antipsychotics and other treatments, as well as the risks of not using medication, so that they can participate effectively in clinical decision-making. Documentation of informed consent should be obtained.

The use of antipsychotics in those with dementia is controversial due to the FDA black box warning regarding the increased incidence of cerebrovascular events and death associated with antipsychotic use. While the effectiveness of antipsychotics for noncognitive symptoms in dementia may be marginal, a short-term trial is generally warranted to control symptoms of mania, psychosis, hallucinations, and aggressive behaviors that could endanger others. While there is no significant difference in effectiveness between FGAs and SGAs, SGAs are generally preferred due to better side effect profiles, particularly in terms of extrapyramidal side effects and tardive dyskinesia. SGAs with evidence for managing behavioral symptoms of dementia include aripiprazole [Abilify], olanzapine [Zyprexa], quetiapine [Seroquel], and risperidone [Risperdal]. Antipsychotics should be used in the lowest effective doses and carefully monitored for adverse events.

The decision to discontinue antipsychotics in patients who have responded to the drug must be carefully weighed against the possibility of worsening symptoms. If the patient experiences significant adverse effects or there is no significant response after 4 weeks of treatment, consideration should be made to taper or withdraw the medication. A Cochrane Database review concluded that chronic antipsychotics may be withdrawn from patients without risking worsening of behavioral symptoms, especially in those with mild neuropsychiatric symptoms. Due to the low number and quality of studies, it is unknown whether the discontinuation of antipsychotics affects cognitive function, quality of life, or mortality rates.

Parkinson Disease With Psychosis

Psychotic symptoms can occur in up to 40% of patients with Parkinson disease. The symptoms may be present continuously or intermittently over the course of a month and predominantly consist of hallucinations. Most hallucinations are visual, and of these, half of the patients also have auditory hallucinations. Hallucinations also tend to be different from schizophrenia and generally have less “emotional content.” Delusions can occur in 5% to 10% of patients treated with antiparkinsonian drugs, and patients are typically paranoid in nature, such as in spousal infidelity. Psychosis is stressful for patients and can potentially cause more distress to caregivers. Psychosis is a poor prognostic indicator for institutionalization, dementia, and mortality. Managing psychosis is one of the most difficult challenges in the care of patients with Parkinson disease. Dopaminergic drugs that can improve the motor disability caused by Parkinson disease are associated with the emergence of psychotic symptoms and appear to be dose-related. Conversely, the use of antipsychotic drugs to reduce psychosis can exacerbate motor symptoms of parkinsonism. Additionally, anticholinergic medications can cause delirium with agitated behavior or psychosis. Management of psychosis in Parkinson disease begins with withdrawal or lowering of the dose of the dopaminergic agent without disrupting motor signs. Due to the complexity of balancing the dopaminergic requirement to control both symptoms, psychosis presents a serious threat to the patient’s ability to maintain independence. If psychosis persists, antipsychotic medications with the lowest liability for exacerbating parkinsonism may be helpful (clozapine [Clozaril] and quetiapine). Pimavanserin [Nuplazid] is an antipsychotic with inverse agonist and antagonist activity at 5-HT2A and 5-HT2C receptors. It is approved for use in the treatment of hallucinations and delusions associated with Parkinson disease psychosis. The most common adverse reactions include gastrointestinal disorders, peripheral edema, a confusional state, and hallucination.

Delirium

Delirium is a cognitive disorder that is characterized by fluctuating levels of consciousness, inattention, memory impairment, and perceptual disturbances. Delirium may be accompanied by illusions, visual hallucinations, and delusions. Delirium can arise from the acute onset of a new medical illness, an exacerbation of a pre-existing chronic illness, a drug reaction or interaction, fever, or trauma. A careful medical, neurologic, and laboratory evaluation to identify the conditions that are contributing to the mental status change is required. Drugs with anticholinergic properties are common causes of delirium in older adults. Recognition and treatment of delirium are important to reduce the risks of morbidity and mortality in these patients. Nonpharmacologic treatment, such as environmental changes, behavioral support, and redirection, are key strategies for treating delirium. Antipsychotics should be prescribed only when necessary to maintain safety and basic care. The lowest effective dosage should be used for a minimum duration for high-risk symptoms that pose safety concerns to the patient or staff. Antipsychotics should also be discontinued or have a plan for tapering once delirium symptoms have resolved.

Depression

Patients with delirium and dementia are at high risk of depression, and depression may be a predictor of cognitive decline. Suicide risk assessment is also important since suicidal ideation can be seen in up to 30% of older adults with major depression. Psychotic symptoms may also occur in patients suffering from depression. In contrast to nonpsychotic depression, older adult patients with psychotic depression are at increased risk for relapse, suicide, and hospitalization. Major depressive disorder with psychotic features responds better to treatment with a combination of an antipsychotic and an antidepressant than to treatment with either agent alone. Electroconvulsive therapy is highly effective in major depressive disorder with psychotic features and, at times, may be considered a first-line treatment, even in older adults. Aripiprazole, brexpiprazole (Rexulti), quetiapine, and olanzapine in combination with fluoxetine (Prozac, Symbyax for combination product), are also indicated for adjunctive treatment for nonpsychotic depression; however, the benefit of using multiple medications that may present adherence challenges and drug–drug interactions in older adult patients must be clearly warranted.

Bipolar Disorder

Bipolar disorder is not uncommon in older adults and often leads to functional impairment and substantial utilization of health care resources. While conventional mood stabilizers such as lithium and valproate are still widely used for bipolar disorder, SGAs have also emerged as first-line options for the control of manic symptoms. Currently, aripiprazole, asenapine (Saphris), cariprazine (Vraylar), olanzapine, quetiapine, risperidone, and ziprasidone (Geodon) are approved for mania. Aripiprazole, quetiapine, and ziprasidone are also indicated for bipolar maintenance treatment, while quetiapine, olanzapine/fluoxetine, and lurasidone (Latuda) are also indicated for bipolar depression. SGAs may offer advantages over drugs like lithium due to their wider therapeutic range and fewer drug–drug interactions. However, metabolic and cardiovascular considerations should still be considered in older adult patients. Unfortunately, comparative effectiveness or safety data for antipsychotics in older adults with bipolar disorder are lacking.

TREATMENT PRINCIPLES

Pretreatment Evaluation

Older adult persons who present with new-onset psychosis, an exacerbation of psychosis, or severe behavioral disturbance should have a thorough medical examination (including neurologic assessment) prior to initiating a new or modifying a pre-existing antipsychotic regimen. At a minimum, the evaluation should include a comprehensive history, physical examination, and laboratory screening, including a toxicology screen for substances of abuse. This may identify medical or substance-induced problems that may be contributing to the behavioral disturbances (e.g., infection or pain) or that may represent a special concern during treatment (e.g., recent myocardial infarction).

Antipsychotic Selection

The choice of an antipsychotic is usually based on a number of factors, and selection should be highly individualized. Factors include specific symptoms, experience with previous treatment (efficacy and side effects), simplicity of regimen (available dosage forms, avoidance of drug interactions, ease of obtaining a therapeutic dose), and cost considerations. With few exceptions, there is limited evidence for the superior efficacy of one antipsychotic over another, and clinicians should base their decision on the above patient-specific factors.

Dosage Forms

Although all antipsychotics are available in oral formulations, only a few are available as injectables (e.g., olanzapine, aripiprazole, ziprasidone, risperidone, and paliperidone [Invega]). Short-acting intramuscular preparations of an antipsychotic may be preferred over oral medications if a patient is agitated and not likely to be cooperative. Intramuscular preparations bypass the gastrointestinal tract and first-pass metabolism and have a faster onset of action. For example, most short-acting intramuscular antipsychotics reach a maximum plasma level within 30 to 60 minutes, and clinical effects are seen within 15 minutes. While short-acting intramuscular preparations offer administration advantages, care should be taken to avoid repeating doses without first assessing for a response or adverse effects. Alternatively, rapidly dissolving tablet formulations (e.g., clozapine, risperidone, olanzapine, aripiprazole) and sublingual tablets (e.g., asenapine) offer the advantage of improved adherence in some patients who have difficulty with swallowing, resistant to taking medications, or prone to behaviors such as “cheeking” medications. Except for people with schizophrenia or schizoaffective disorder with a history of poor medication-taking behaviors, long-acting depot medications are not usually prescribed for older adults with psychosis.

Table 55.4d–2.
Recommended Dosing Guidelines for Antipsychotics

		Dementia		Schizophrenia	
Medication	Brand Name	Initial Dosage in Older Adult Patients (mg/day)[a]	Usual Maximum Dosage in Older Adult Patients (mg/day)[a]	Initial Dosage in Older Adult Patients (mg/day)[a]	Usual Maximum Dosage in Older Adult Patients (mg/day)[a]
Haloperidol	Haldol	0.25–0.50	0.25–2.0	0.5–1.0	5.0
Clozapine	Clozaril	12.5	75–100	12.5–25.0	100–300
Risperidone	Risperdal	0.25–1.0	1.0–2.0	0.5–2.0	2.0–4.0
Olanzapine	Zyprexa	1.25–5.0	10	2.5–5.0	5.0–15.0
Quetiapine	Seroquel	12.5–50	200–300	12.5–50.0	50–300
Ziprasidone	Geodon	20	Unknown	20	Unknown
Aripiprazole	Abilify	5	15	5–10	10–30
Paliperidone	Invega	3	Unknown	3	3–12
Asenapine[b]	Saphris	10	Unknown	10	20
Iloperidone[b]	Fanapt	2	Unknown	2	24
Lurasidone[b]	Latuda	40	Unknown	40	160
Brexpiprazole[b]	Latuda	1	Unknown	1	4
Lumateperone[b]	Caplyta	42	Unknown	42	42
Cariprazine	Vraylar	1.5	Unknown	1.5–3	3–6

[a] Routine orally administered initial and maximum dosage ranges are listed. Higher or lower doses may be indicated in some cases.
[b] Optimal dosage ranges listed are based on limited experience.

General Dosing Recommendations

There is considerable heterogeneity in age-related pharmacokinetic and pharmacodynamic alterations. Thus, the efficacy and adverse effects of a particular antipsychotic dosage may vary considerably. In addition, the time required for antipsychotic response is typically longer than in younger patients. The initial dosage should be relatively low, and dose increases should be titrated cautiously but up to an effective level. Antipsychotic medication dosage in an older patient with a primary psychotic disorder (e.g., schizophrenia) is usually one-half the usual dosage in young patients, although some older patients will respond best to the higher dosages typically prescribed for younger patients. Optimal medication dosage for older patients with a primarily cognitive or neurologic disorder (e.g., dementia) and psychosis is usually 25% to 50% of doses typically prescribed to younger patients (Table 55.4d–2).

Adherence Issues

Older patients commonly take several medications simultaneously and therefore have an increased risk of adverse drug reactions. A complete drug history should be obtained, and concomitant medications simplified, if possible, prior to implementing antipsychotic treatment. Medication adherence is a problem in all age groups, but older adults may be especially susceptible to adherence challenges. Physical problems, such as impaired vision, may increase the likelihood that instructions will be misread or that one medicine will be mistaken for another. Patients with cognitive impairment may forget to take their medication, and drug regimens with complex administration schedules should be avoided. Drug administration issues also present challenges for older adult patients, such as special handling requirements for asenapine (handle with dry hands, no food or liquid for 10 minutes after dose) and dietary requirements for ziprasidone and lurasidone (350 to 500 kcal required with dose). Psychological factors, such as fear of side effects or becoming dependent on medications, may also affect adherence.

Table 55.4d–3.
Dosage Formulations and Drug Interaction Potential for Selected Antipsychotics

			Drug Interaction Potential	
Medication	Brand Name	Available Dosage Forms	Pharmacokinetic: Major Cytochrome P450 Pathway	Pharmacodynamic: Medications With the Following Effects May Exacerbate Adverse Effect Profile of Atypical Antipsychotic
Haloperidol	Haldol	T, S, IM, LA	2D6	Anticholinergic, CNS effects
Clozapine	Clozaril	T, ODT	1A2, 2D6, 3A4	Anticholinergic, bone marrow suppressors, CNS effects, hypotension
Risperidone	Risperdal	T, S, ODT, LA	2D6	CNS effects, hypotension
Olanzapine	Zyprexa	T, ODT, IM, LA	1A2	Anticholinergic, CNS effects, hypotension
Quetiapine	Seroquel	T, XR	3A4	CNS effects, hypotension
Ziprasidone	Geodon	C, IM	3A4 (minor)	CNS effects, hypotension, QTc prolongation
Aripiprazole	Abilify	T, IM, S, ODT, LA	2D6, 3A4	CNS effects
Paliperidone	Invega	T, LA	2D6 (limited), 3A4 (limited)	CNS effects
Asenapine	Saphris	ODT	1A2, 2D6	CNS effects, hypotension
Iloperidone	Fanapt	T	2D6, 3A4	CNS effects, hypotension, QTc prolongation
Lurasidone	Latuda	T	3A4	CNS effects
Brexpiprazole	Rexulti	T	3A4, 2D6	CNS effects
Lumateperone	Caplyta	C	3A4	CNS effects
Cariprazine	Vraylar	C	3A4, 2D6	CNS effects

Dosage forms: C, capsule; CNS, central nervous system; IM, short-acting intramuscular injection; LA, long-acting intramuscular injection; ODT, orally disintegrating tablet/granule; S, solution; T, tablet; XR, extended-release oral tablet.

Drug Interactions

Both pharmacokinetic and pharmacodynamic drug interactions can occur with antipsychotic agents. Cytochrome P450 (CYP) enzymes, especially 1A2, 2D6, and 3A4, are responsible for the metabolism of many antipsychotics. In general, antipsychotics are primarily metabolized hepatically by CYP enzymes but are not major inducers or inhibitors of CYP-mediated metabolism. Thus, antipsychotics do not commonly affect the pharmacokinetics of other medications but are themselves affected by other medications. Induction or inhibition of these enzymes by other drugs may occasionally provide clinically important drug interactions. Drugs that have the potential to have serious interactions with antipsychotics include fluvoxamine (1A2 inhibitor); erythromycin, ketoconazole, and ritonavir (3A4 inhibitors); quinidine, risperidone, fluoxetine, and paroxetine (2D6 inhibitors); and cimetidine (multiple systems). Conversely, enzyme inducers such as carbamazepine (3A4) or cigarette smoking (1A2) can reduce plasma concentrations of antipsychotic drugs by increasing the metabolism of the antipsychotic agent and lead to less-than-effective plasma concentration. For example, carbamazepine has been shown to reduce plasma concentrations of haloperidol by 50%. Cigarette smoking (1A2) has been shown to increase the clearance rate of clozapine and olanzapine. A pharmacodynamic interaction occurs when medications with similar unwanted properties are concurrently prescribed, such as low-potency FGAs or clozapine, with other drugs possessing strong anticholinergic effects (e.g., diphenhydramine or hydroxyzine). Pharmacodynamic drug interactions of greatest concern involve additive orthostasis, anticholinergic effects, QTc prolongation, and sedation (Table 55.4d–3).

PRECAUTIONS AND ADVERSE REACTIONS

Mortality

The black box labeling of antipsychotics by the FDA was prompted by 15 placebo-controlled trials that showed a 1.6- to 1.7-fold increased risk of death among those with dementia taking atypical antipsychotics. Specific causes of these deaths were attributed to heart-related events (e.g., heart failure, sudden death) or infections (mostly pneumonia). In a study of older Veterans, the risk of 10-year all-cause mortality was highest among those with dementia and prescribed antipsychotics (78%) compared to those without dementia or exposed to antipsychotics (42%). In a meta-analysis of 17 studies, there was no difference among antipsychotics for the primary safety outcome of death. In another systematic review and meta-analysis of 352 placebo-controlled studies in schizophrenia, there was no difference between antipsychotic drugs and placebo in mortality by any cause.

Cerebrovascular Events

Cerebrovascular adverse events, such as strokes, transient ischemic attacks, and fatalities, have been observed in older adult patients with dementia-related psychosis prescribed with aripiprazole, olanzapine, quetiapine, or risperidone. In 17 placebo-controlled trials, a higher number of cerebrovascular adverse events were observed in patients treated with SGAs compared to patients treated with a placebo. Data analyses have suggested that increased age (older than 80 years), concurrent use of benzodiazepines, sedation, pulmonary infections (pneumonia), and medical risks (prior strokes, hypertension, coronary artery disease, and hyperlipidemia) may increase the risk of experiencing a cerebrovascular adverse event.

Whether the mortality and cerebrovascular adverse event risks have a similar underlying mechanism is yet unclear. In a study of over 30,000 Medicare and Patient Assistance Program enrollees, FGAs were associated with higher risks of stroke and death compared with SGAs over 180 days. Interestingly, stroke did not explain the difference in mortality risk between the two drug groups. Orthostatic hypotension seems a likely mediating variable in some patients, as well as falls and oversedation.

Weight Gain

Weight gain has been associated with FGAs and SGAs in young and older adults. Weight gain is most prominent within the first 4 to 12 weeks of treatment with antipsychotics, especially SGAs. The cause of antipsychotic-induced weight gain is multifactorial and may include a change in food preferences, increased food or fluid intake, carbohydrate craving, or a sedentary lifestyle. Blockade of the histamine and 5-HT_{2C} receptors are also contributory. Histamine H_1

blockade causes sedation that may produce inactivity. H_1 blockade may also increase weight by interfering with normal satiety signals from the gut, resulting in overeating. In the CATIE-AD study, older adult patients who were treated with olanzapine, quetiapine, or risperidone had an average weight gain of 1.0, 0.7, and 0.4 lb, respectively, compared with a monthly weight loss of 0.9 lb for those who received placebo. Weight gain was more prominent in those with a BMI of less than 25 at baseline, and this is consistently seen in other age groups. Clozapine has also been associated with significant weight gain. Weight gain associated with antipsychotic treatment should be taken seriously because it may contribute to or exacerbate medical conditions such as diabetes, coronary artery disease, and hypertension. If significant weight gain is observed, a switch to another antipsychotic with lower weight gain liability may be considered as long as treatment effectiveness is not compromised.

Metabolic Effects

Diabetes mellitus and other metabolic disorders have been shown to be more common in adult and older adult patients with schizophrenia than in the general population. FGAs and SGAs that are used to treat schizophrenia can also worsen glucose intolerance, diabetes, and hypertriglyceridemia in those with or without a history of diabetes mellitus. In rare incidences, these events may lead to diabetic ketoacidosis and death. These complications may or may not be associated with weight gain. Clozapine and olanzapine have been associated with a 1.3- to 1.4-fold higher prevalence of diabetes, followed by quetiapine and risperidone. Potential mechanisms for glucose dysfunction include H_1-receptor antagonism, 5-HT_{2C}-receptor antagonism, reduced functioning of pancreatic cells or pancreatic cell damage, and altered regulation of insulin resistance. In older patients with various psychiatric disorders (e.g., schizophrenia, mood disorders, PTSD, or dementia), treatment with antipsychotics (aripiprazole, olanzapine, quetiapine, and risperidone) for at least 6 months was associated with a high incidence of metabolic syndrome. Body mass index, blood pressure, fasting blood glucose, LDL and

HDL cholesterol, and triglycerides were the primary metabolic markers studied. Patients also experienced serious and nonserious adverse events at the 2-year follow-up (23.7% and 50.8%, respectively). In addition, there was no significant change in psychopathology associated with any of the SGAs in the study. Hypertriglyceridemia seems to be due to increased adiposity resulting in higher free fatty acid concentration, insulin resistance, and increased VLDL production. Clozapine and olanzapine, again, have been associated with higher risks of hypertriglyceridemia compared to other antipsychotics in non–older adult patients. In the CATIE-AD trial and other systematic reviews, the association of weight gain and BMI was demonstrated with SGAs, but there was no association with glucose, total cholesterol, and triglyceride levels. The impact of metabolic syndrome and other adverse events on the overall health of older adult patients must be considered in the decision to use these drugs, and careful and proactive monitoring of weight, glucose levels, and lipid panel is warranted.

Tardive Dyskinesia

Tardive dyskinesia is a syndrome characterized by abnormal involuntary movements, typically involving the orofacial region, limbs, and trunk. Essential features of tardive dyskinesia include involuntary movements of the tongue, face, and jaw. Most tardive dyskinesia cases are relatively mild. In some older patients, a form of tardive dyskinesia may develop that is severe enough to impair functioning. Severe oral dyskinesia may result in dental and denture problems that can progress to ulceration and infection of the mouth as well as muffled or unintelligible speech. Severe orofacial tardive dyskinesia can impair eating and swallowing, which in turn can produce significant health problems. Gait disturbances due to limb dyskinesia may leave patients vulnerable to falls and injuries. Increasing age is the most consistently observed risk factor for the development of tardive dyskinesia. The annual incidence rates of developing tardive dyskinesia are three- to fivefold greater in older patients compared to younger adults. In addition, older adult patients seem to have earlier tardive dyskinesia symptoms and have more persistent symptoms than younger patients. Other risk factors include higher mean daily and cumulative antipsychotic doses and the presence of extrapyramidal signs early in treatment. The risk of antipsychotic-induced tardive dyskinesia is suggested to be lower with SGAs compared to FGAs. This lower risk was confirmed in a 2-year study of risperidone and olanzapine in antipsychotic-naïve older adult patients. There is some indication that the risk of tardive dyskinesia may be higher in women, non-Whites, patients with affective psychiatric disorders, and patients taking concomitant anticholinergic agents; however, the heterogeneity of available studies makes it challenging to determine this association conclusively.

Anticholinergic Side Effects

Older adult patients are much more sensitive to the anticholinergic side effects of medications than younger adults. Anticholinergic medications may aggravate existing comorbidities or concomitant medications with anticholinergic properties in older adult patients. Peripheral anticholinergic symptoms may include dry mouth, constipation, urinary retention, tachycardia, blurred vision, and aggravation of narrow-angle glaucoma. Dry mouth may cause problems with dentures; constipation may lead to ileus and perforation; urinary retention may be further aggravated by prostatic hypertrophy, and blurred vision may further aggravate pre-existing visual problems.

The central muscarinic blockade in older adults also increases their risk for delirium and impaired cognition, attention, memory, and self-care capacity. The higher risk of falls and hip fractures associated with antipsychotics in older adults is due in part to the anticholinergic, sedative, and orthostatic properties of these medications. In some cases, anticholinergic toxicity may be mistaken for an exacerbation of psychosis, and the antipsychotic dose may be increased inappropriately. Severe anticholinergic symptoms due to high doses of antipsychotics may manifest as increased irritability, aggressiveness, and visual hallucinations.

Sedation

Sedation is a common side effect of antipsychotics that can increase the risk of confusion and falls in older adults. Antipsychotics with sedative properties are often prescribed to calm agitated patients or to treat sleep disturbances. In a comparative effectiveness review, sedation was more common in older adult patients taking olanzapine or quetiapine than risperidone, but this was not statistically significant. Sedation is likely to occur in older adults at much lower doses than those prescribed to younger patients, and older adult patients are at risk for developing daytime sedation from the residual effects of nighttime dosing of the antipsychotic. Older adult patients may appear confused or have other cognitive impairments due to oversedation and should be evaluated appropriately.

Hypotension

Because of decreased adrenergic tone and cardiac output, older adult patients may be more vulnerable to orthostatic effects and may have severe orthostasis at relatively low doses. Orthostatic episodes are most likely to appear early in treatment, and the patient should be monitored closely during this period. Patients (or their caregivers) should be instructed to rise slowly after being seated or supine and take extreme care if they awaken during the night. The lowest doses of antipsychotics should be used, and patients should be adequately hydrated throughout the day.

Cardiovascular Effects

In addition to orthostatic hypotension, antipsychotics may also cause tachycardia and electrocardiogram (ECG) changes. Tachycardia may occur as a result of the anticholinergic effects of antipsychotic medications on vagal inhibition or secondary to orthostatic hypotension. ECG changes such as prolongation of the QT and PR intervals, ST-segment depression, and T-wave flattening have been observed with antipsychotics. The most clinically important ECG change is a prolongation of the QTc interval (which is the QT interval adjusted for heart rate). QTc prolongation may lead to the development of ventricular tachyarrhythmias such as torsades de pointes and ventricular fibrillation, that may result in syncope, cardiac arrest, or sudden cardiac death. All antipsychotics have the potential to prolong the QTc interval but to varying degrees. Thioridazine, pimozide, IV haloperidol, ziprasidone, and iloperidone (Fanapt) appear to have the largest effect on QTc interval. Effects are usually dose-related, although that may not be the case for ziprasidone or iloperidone. Other risk factors for QTc prolongation and torsades de pointes include advanced age, female gender, and electrolyte imbalance (hypokalemia, hypomagnesemia). Patients with a history of syncope, cardiac disease, electrolyte imbalance, or a family history of early sudden cardiac death should have an ECG before antipsychotic treatment. While thioridazine and pimozide are no longer clinically used, IV haloperidol, ziprasidone, and iloperidone are still therapeutic options for patients with schizophrenia. These drugs should be avoided in patients with a known history of QTc prolongation, recent acute myocardial infarction, or uncompensated heart failure. Clinical and ECG monitoring of cardiac function is recommended during antipsychotic therapy, particularly in patients treated with antipsychotics with known higher risks of QTc prolongation or those who have symptoms that could indicate torsades de pointes (e.g., dizziness, palpitations, syncope). These agents should also not be prescribed with other drugs that prolong the QT interval.

Other Adverse Effects

Clozapine use is associated with a dose-related risk of seizures and is the only antipsychotic agent associated with the rare development of myocarditis. In rare cases, orthostatic hypotension can be accompanied by cardiac collapse and/or cardiac arrest. Due to clozapine's significant risk of agranulocytosis, mandatory monitoring of white blood cell count and absolute neutrophil count is required. Age and certain ethnicities appear to be risk factors for the development of agranulocytosis. Clozapine, thus, is used specifically in patients for whom multiple therapies are inadequate or not tolerated or who have severe tardive dyskinesia.

55.4e Antidementia Drugs

IQBAL AHMED, M.D., F.R.C.PSYCH.

The medications available for prescription in the United States for treating Alzheimer disease include cholinesterase inhibitors, donepezil rivastigmine, galantamine, and the noncompetitive *N*-methyl-D-aspartate (NMDA) antagonist memantine. The cholinesterase inhibitors are specifically indicated in their U.S. Food and Drug Administration (FDA)–approved labeling for "the treatment of mild to moderate dementia of the Alzheimer type." Donepezil and rivastigmine transdermal are further indicated for severe Alzheimer disease as well. Rivastigmine also has approved labeling for "the treatment of mild to moderate dementia of Parkinson's disease." Memantine is indicated for the treatment of moderate to severe Alzheimer disease; the FDA specifically did not approve an indication for its use in mild Alzheimer disease. A capsule containing both donepezil and memantine is also marketed for moderate to severe Alzheimer disease. These drugs, thus, are considered "antidementia" drugs.

Antidementia drugs are, by definition, medications intended to improve cognitive function in patients with dementia. The term has regulatory significance with the FDA because it differentiates these medications from “cognitive enhancers,” medications that might be expected to improve cognition without reference to a particular illness, and from medications that might improve such behavioral syndromes as depression, aggression, or psychosis in people with dementia.

Worldwide, a range of putative cognitive enhancing agents is offered with and without prescription, including piracetam derivatives, cholinesterase inhibitors, an NMDA antagonist, memantine, selegiline, antioxidants, vitamins, food supplements, so-called nutraceuticals, and various plant derivatives, including *Ginkgo biloba* standardized extract. In the United States, food supplements and nutraceuticals are regulated by the FDA only with respect to apparent safety and inappropriate advertising claims. No specific health claim or disease-treatment claim should be made by the marketers of nutraceuticals and food supplements, and efficacy evidence for the conditions being treated does not have to be addressed. Rather, marketers of nutraceuticals and food supplements may make a “structure/function claim,” characterizing the supplement as intended to affect normal structure or function or the mechanism by which it acts to maintain such structure or function (21 CFR 101.93).

Although it has been suggested that other medications available in the United States might have efficacy in patients with Alzheimer disease, clinical trial results indicate that selegiline, vitamin E, *Ginkgo biloba* extract, conjugated estrogens, and anti-inflammatories do not have salutary effects—in some cases, they have cognitively impairing effects—and should not be used to treat dementia.

Alzheimer disease is the most common dementia associated with aging and hence is the most common target for antidementia therapeutics. Vascular dementia, dementia with Lewy bodies, Parkinson disease dementia, frontotemporal dementia, and dementias associated with hippocampal sclerosis are less common, although there is a large degree of overlap of the pathology of Alzheimer disease with these other pathologies.

Although the causes of Alzheimer disease are unknown, except for rare early-onset familial and genetic cases, a substantial part of the pathophysiology is sufficiently understood to allow for the rational development of symptomatic or potentially disease-modifying treatments.

The framework for clinical trials in Alzheimer disease developed slowly during the last two decades after the advent and general acceptance of research-based diagnostic criteria for the dementia of Alzheimer disease (i.e., the essentially identical National Institute of Neurological Communicative Disorder [NINCDS] Alzheimer's Disease and Related Disorders Association [ADRDA] criteria for probable Alzheimer disease, and the *Diagnostic and Statistical Manual of Mental Disorders,* fourth edition text revision [DSM-IV-TR] criteria for dementia of the Alzheimer type), a better understanding of its underlying pathology, and the development of mechanism-based pharmacologic therapeutics. For example, the pathophysiology of Alzheimer disease is characterized, in part, by early loss of synapses, death of neurons, the deposition of insoluble β-amyloid peptide fragments, atypical inflammatory responses, and the excess production of toxic, oxidizing free radicals, thus providing targets for drug development.

Until the 1980s, medications were proposed for dementia treatment based on clinical experience or prevailing theories of dementia and aging. Examples of such earlier claimed treatments (and their rationale) include nonspecific psychostimulants (to increase arousal), vasodilators (to increase blood flow), and hyperbaric oxygen (to enhance metabolism). One medication, ergoloid mesylates, was approved in the United States for the ill-defined condition "senile mental decline," a condition based on vague diagnostic constructs, such as "cerebral insufficiency" or "cerebral deterioration." The mechanism of action of ergoloid mesylates is unknown but may involve effects on complex neurotransmitter and vascular effects. However, it is no longer available or marketed in the United States.

REGULATORY AND METHODOLOGIC CONSIDERATIONS

FDA guidelines for establishing that a drug has antidementia efficacy include requirements that patients meet accepted diagnostic criteria for a primary well-accepted dementia, such as Alzheimer disease; that trials use double-blind, placebo-controlled parallel-group designs; that at least one trial is of 6 months duration; and that improvement is obtained on an accepted cognitive instrument and a clinician’s global assessment, to ensure a clinically meaningful effect as compared to a potentially measurable but trivial cognitive effect. Improvements in activities of daily living also may be considered as an index of clinical meaning in lieu of clinical global assessments.

From a regulatory perspective, behavioral changes as a result of treatment are of secondary importance despite the clinical importance of such improvement. Specifically, improvement in behavior or functional activities in the absence of improved cognition is not a sufficient outcome for allowing a drug to be labeled “antidementia.” A concern is that antidepressants or antipsychotics might be misleadingly advertised as being effective for dementia when their intended use is to treat depressive or psychotic symptoms or aggression.

For clinical trials in Alzheimer disease, the Alzheimer’s Disease Assessment Scale—cognitive subscale (ADAS-cog) has become the standard cognitive change measure, and a clinician’s interview-based impression of change instrument or activities of daily living inventory has become the measure of “clinical meaningfulness.” The ADAS-cog provides a summary score reflecting measures of word recall, naming, following commands, constructional and ideational praxis, orientation, word recognition, spoken language, comprehension of spoken language, word finding, and recall of test instructions. Although it has proven itself sufficiently sensitive to change with cholinesterase inhibitor treatments in mild to moderate Alzheimer disease, it is not as sensitive to change in mild dementia and mild cognitive impairment (MCI) due to Alzheimer disease (also known as prodromal Alzheimer disease), and people with severe dementia have difficulty performing the test. More recently, another cognitive battery, the Severe Impairment Battery, has been used as an index of cognitive change in Alzheimer disease trials of patients who are moderate to more severely cognitively impaired. It is a group of brief tests assessing social interaction, memory, orientation, language, attention, praxis, and construction.

For mild Alzheimer disease and MCI due to Alzheimer disease, a Neuropsychological Test Battery (an NTB) has been offered that—in its most common form—consists of three tests of immediate and delayed memory, verbal and category fluency, and digit span; and the Repeatable Battery For The Assessment of Neuropsychological Status (RBANS) which similarly assesses memory, language, attention, and visuospatial/constructional ability. Regulatory guidelines for marketing approval do not exist for the treatment of other dementias (e.g., vascular dementia, dementia with Lewy bodies, frontotemporal dementia), MCI (other than MCI due to Alzheimer disease), other cognitive disorders, or age-related cognitive decline or for cognitively unimpaired persons, mainly because of a lack of general expert consensus on the validity of the proposed diagnostic criteria. One exception is Parkinson disease associated mild to moderate dementia for which rivastigmine is approved by the FDA for this indication.

In 2018, FDA proposed draft guidelines for the clinical development of drugs for early-stage Alzheimer disease, including the entities MCI due to Alzheimer disease and preclinical Alzheimer disease. The guidelines allow for only a composite outcome, including assessments of cognition and function combined in order to approve a drug for MCI and a single cognitive outcome for provisional approval for a drug for preclinical Alzheimer disease. No drugs have been approved under these guidelines.

Although there are efforts to gain recognition of functionally significant but mild cognitive loss, such as age-associated memory impairment, in which cognition is lower than a young adult comparison, or age-related cognitive decline, in which memory is impaired compared to an age-appropriate comparison, the vagueness of the definitions and underlying pathology limits their general acceptance, and hence the acceptance of “treatments” for such unrecognized conditions. People with age-associated memory impairment generally do not worsen cognitively at a rate greater than the population, whereas those with MCI have an increased rate of worsening and developing dementia. The results of several clinical trials for improving cognition in MCI using the cholinesterase inhibitors donepezil, galantamine, and rivastigmine and vitamin E, anti-inflammatories, and piracetam (Nootropil) have not shown significant cognitive effects for the drugs.

With respect to unimpaired older persons, nearly all of whom can claim that memory, learning, and other aspects of cognition are not as good as they used to be, there are societal questions about the appropriateness of treatment with cognitive enhancers even if they are demonstrated to be effective. Similarly, generally accepted guidelines do not exist for the treatment of cognitive deficits associated with schizophrenia, attention-deficit disorder, or depression, despite general recognition that these cognitive deficits are important areas of clinical attention. There have been attempts to provide clinical criteria for “cognitive impairment associated with schizophrenia” and cognitive outcomes criteria for clinical trials.

PHARMACOLOGIC TREATMENT OF SYMPTOMATIC BEHAVIORS OR BEHAVIORAL AND PSYCHOLOGICAL SYMPTOMS OF DEMENTIA

The majority of patients with Alzheimer disease experience such behavioral symptoms as depression, anxiety, psychosis, agitation, aggression, apathy, withdrawal, and vegetative disturbances (e.g., sleep or appetite change). These signs and symptoms frequently lead to the use of psychotropic medication treatment (both appropriate and inappropriate), physical restraint, and institutionalization. Behavioral symptoms burden caregivers and are considered among the most stressful aspects of caregiving. A variety of psychotropic medications, however, may be effective for pharmacologic intervention and improve many of these symptoms. Evidence suggests that these symptoms occurring in the context of Alzheimer disease can represent manifestations of two syndromes: psychosis of Alzheimer disease and depression of Alzheimer disease.

The treatment of symptomatic behaviors begins with careful characterization of the target symptoms. Such symptoms as agitation, aggression, or delusions can result from chronic or recurrent psychiatric disorders, represent the first manifestation of a new psychiatric disorder, or indicate a change in medical status. (The term *agitation* often is used to describe a range of nonspecific behaviors in older adults beyond excess psychomotor activity, including wandering, pacing, uncooperativeness, and verbal outbursts. Similarly, the commonly used phrase *behavioral and psychological disorders of dementia* is vague and unspecific and probably should not be used.) A comprehensive medical evaluation might uncover potentially treatable underlying physical conditions that can exacerbate behaviors. Moreover, patients with dementia are at increased risk for developing superimposed delirium and consequent disruptive behaviors.

Patients with dementia are sensitive to a variety of factors that may influence behavior, including sensory impairment, environmental disruption, and altered daily routines. Consequently, environmental manipulations may be helpful. Many dementia patients experience anger, sadness, and denial, which may improve with psychosocial and psychotherapeutic interventions. Various behavior management techniques, including cognitive-behavioral management, may be helpful for more moderately to severely impaired individuals. Supportive psychotherapy and counseling may be helpful for patients with more MCIs. Caregivers often need greater awareness that their own behaviors influence the patient. Counseling about the nature of the patient’s illness not only helps relatives cope better but also is associated with better outcomes for patients, such as delayed institutionalization.

Although the nonpharmacologic and pharmacologic treatment of symptomatic behaviors in dementia patients is beyond the scope of this section, the suggested interventions are necessary preparatory approaches to the pharmacologic treatment of cognitive impairment as well.

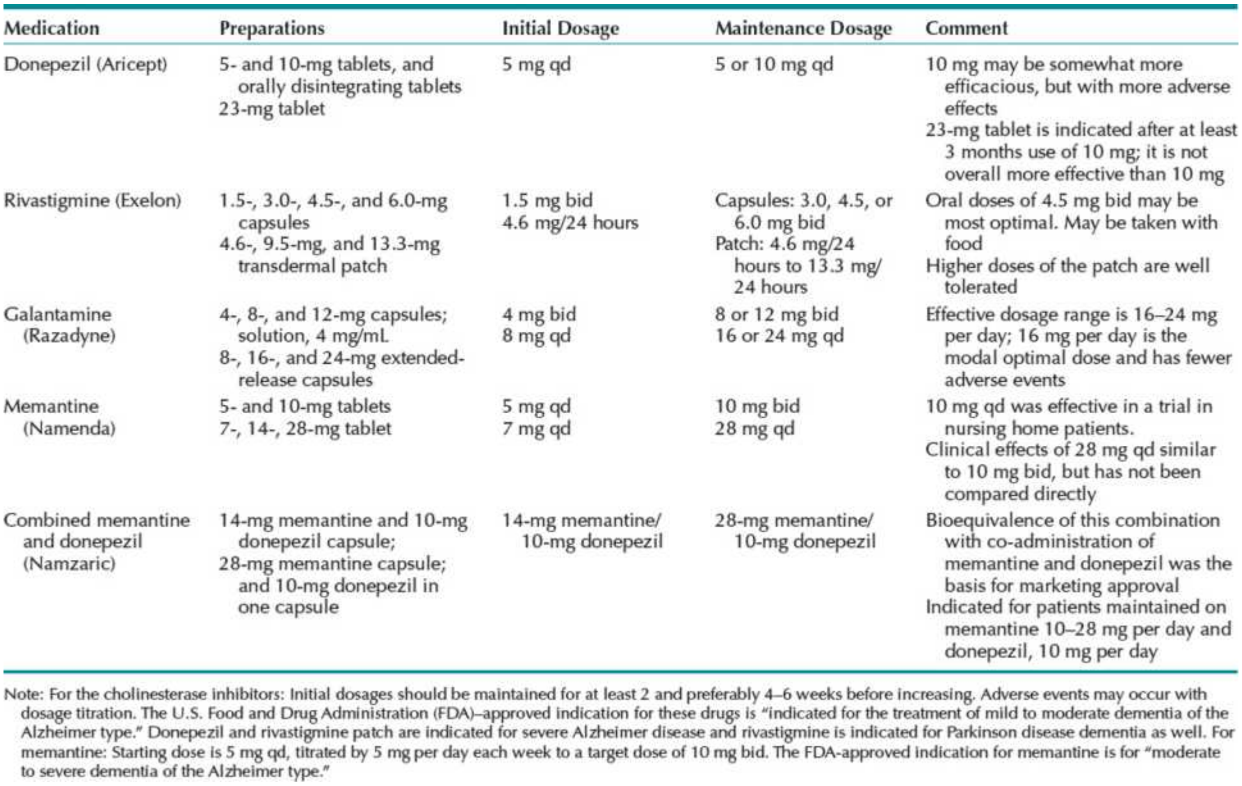
DRUGS TO TREAT DEMENTIA

From a conceptual consideration, antidementia drugs can be grouped into two broad categories: those intended to improve cognitive function symptomatically and those intended to modify the course of illness over the longer term, as manifested by the potential attenuation of cognitive and functional decline. In practice, these two categories overlap. Medication development for dementia typically focuses on one or the other, depending on the mechanism of action of the new drug. The only drugs currently approved, however, are for symptomatic treatment, and their efficacy and FDA marketing approval were based on 6-month-long, placebo-controlled clinical trials. Table 55.4e–1 lists available drugs to treat the cognitive symptoms of dementia.

Cholinergic Hypothesis

The cholinergic hypothesis of dementia is based on observations of a massive decline of the cholinergic projections from the basal forebrain to the cortex; reductions in the activity of choline acetyltransferase, the key enzyme in acetylcholine synthesis; a marked loss of cholinergic cell bodies in the nucleus basalis in Alzheimer disease; correlations between choline acetyltransferase reduction or nucleus basalis cell reduction and neuritic, β-amyloid–containing plaque densities in cortical areas; and correlation of the cholinergic deficits with the decline in cognitive test performance.

Table 55.4e–1. U.S. Food and Drug Administration–Approved and Marketed Medications for Alzheimer Disease



Medication	Preparations	Initial Dosage	Maintenance Dosage	Comment
Donepezil (Aricept)	5- and 10-mg tablets, and orally disintegrating tablets 23-mg tablet	5 mg qd	5 or 10 mg qd	10 mg may be somewhat more efficacious, but with more adverse effects 23-mg tablet is indicated after at least 3 months use of 10 mg; it is not overall more effective than 10 mg
Rivastigmine (Exelon)	1.5-, 3.0-, 4.5-, and 6.0-mg capsules 4.6-, 9.5-mg, and 13.3-mg transdermal patch	1.5 mg bid 4.6 mg/24 hours	Capsules: 3.0, 4.5, or 6.0 mg bid Patch: 4.6 mg/24 hours to 13.3 mg/24 hours	Oral doses of 4.5 mg bid may be most optimal. May be taken with food Higher doses of the patch are well tolerated
Galantamine (Razadyne)	4-, 8-, and 12-mg capsules; solution, 4 mg/mL 8-, 16-, and 24-mg extended-release capsules	4 mg bid 8 mg qd	8 or 12 mg bid 16 or 24 mg qd	Effective dosage range is 16–24 mg per day; 16 mg per day is the modal optimal dose and has fewer adverse events
Memantine (Namenda)	5- and 10-mg tablets 7-, 14-, 28-mg tablet	5 mg qd 7 mg qd	10 mg bid 28 mg qd	10 mg qd was effective in a trial in nursing home patients. Clinical effects of 28 mg qd similar to 10 mg bid, but has not been compared directly
Combined memantine and donepezil (Namzaric)	14-mg memantine and 10-mg donepezil capsule; 28-mg memantine capsule; and 10-mg donepezil in one capsule	14-mg memantine/ 10-mg donepezil	28-mg memantine/ 10-mg donepezil	Bioequivalence of this combination with co-administration of memantine and donepezil was the basis for marketing approval Indicated for patients maintained on memantine 10–28 mg per day and donepezil, 10 mg per day

Note: For the cholinesterase inhibitors: Initial dosages should be maintained for at least 2 and preferably 4–6 weeks before increasing. Adverse events may occur with dosage titration. The U.S. Food and Drug Administration (FDA)–approved indication for these drugs is "indicated for the treatment of mild to moderate dementia of the Alzheimer type." Donepezil and rivastigmine patch are indicated for severe Alzheimer disease and rivastigmine is indicated for Parkinson disease dementia as well. For memantine: Starting dose is 5 mg qd, titrated by 5 mg per day each week to a target dose of 10 mg bid. The FDA-approved indication for memantine is for "moderate to severe dementia of the Alzheimer type."

Many other neuronal systems are affected besides the cholinergic system, including pronounced declines in the noradrenergic projections from locus ceruleus to cortex and general changes in glutamate systems. Notably, there is greater research emphasis on more fundamental pathogenetic processes affecting neurodegeneration, including β-amyloid peptide production and deposition, tau-protein phosphorylation resulting in neurofibrillary tangles, inflammatory responses, and the use of medications that might be neuroprotective.

Nevertheless, the observation that cholinergic deficits represent the most pronounced transmitter deficit throughout the dementia process has led to a considerable focus on cholinergic restitutive strategies. The cholinergic hypothesis of dementia treatment implies that if the cholinergic deficit is responsible for cognitive or behavioral changes, then potentiation of central cholinergic function should improve cognitive and behavioral impairment associated with Alzheimer disease.

Thus far, there have been three main cholinergic approaches to Alzheimer disease treatment: use of precursor loading, use of direct cholinergic agonists, and cholinesterase inhibition.

Precursor Loading and Direct Cholinergic Stimulation

Early investigations focused on the use of acetylcholine precursors, including choline and phosphatidyl choline (lecithin), analogous to the use of dopamine precursors in Parkinson disease. Numerous trials with precursors, however, have not shown significant results, failing to show a reliable improvement in cognitive function. Thus, even though these products are sold in health food stores, their use cannot be recommended.

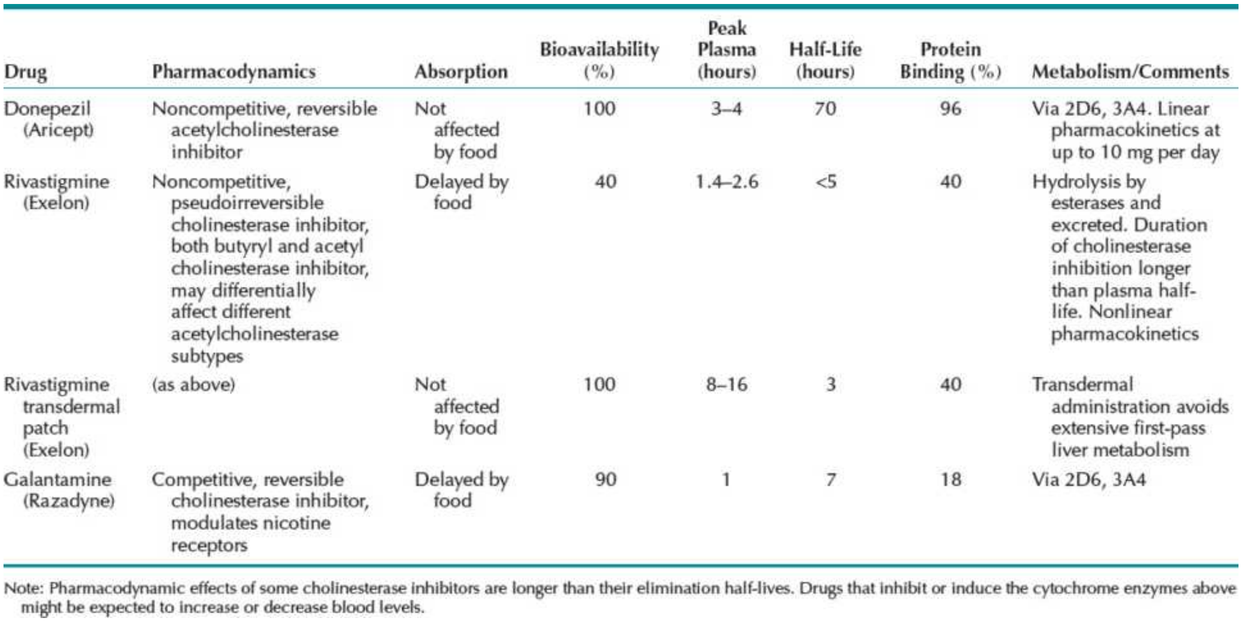
Direct cholinergic agonists enhance responsiveness to released acetylcholine and minimize the presynaptic inhibition of further release by intrasynaptic acetylcholine concentrations. Thus far, however, direct muscarinic or nicotinic receptor agonists have not proven useful in enhancing cognition in Alzheimer disease. The older and newer, relatively more muscarinic receptor subtype-specific investigational medications have not proven useful either. Marketed cholinergic agonists, such as arecoline and bethanechol (brand name, Urecholine), cannot be recommended because of their inadequate central nervous system (CNS) penetration, high frequency of cholinergic side effects, and minimal, if any, efficacy.

Although nicotinic agents currently under development, including transdermal nicotine, nicotinic α_7 receptor modulators, and newer nicotinic α_4, and β_2 receptor modulators, may improve attention, arousal, and concentration in adults, their usefulness in such cognitive impairment syndromes as Alzheimer disease has not been adequately investigated. They also may have a role in attention-deficit disorder and cognitive impairment associated with schizophrenia. So far, none of the two α_7 nicotinic receptor modulators which have been studied have had positive effects on cognition or function.

Cholinesterase Inhibitors

The most successful approach to the treatment of Alzheimer disease thus far has been cholinesterase inhibition. In early studies, physostigmine demonstrated modest cognitive improvements but required individualized and very frequent dosing because of its very short duration of action (1 to 2 hours), thus limiting any potential clinical usefulness.

Table 55.4e–2.
Pharmacodynamics and Pharmacokinetics of Marketed Cholinesterase Inhibitors



Drug	Pharmacodynamics	Absorption	Bioavailability (%)	Peak Plasma (hours)	Half-Life (hours)	Protein Binding (%)	Metabolism/Comments
Donepezil (Aricept)	Noncompetitive, reversible acetylcholinesterase inhibitor	Not affected by food	100	3–4	70	96	Via 2D6, 3A4. Linear pharmacokinetics at up to 10 mg per day
Rivastigmine (Exelon)	Noncompetitive, pseudoirreversible cholinesterase inhibitor, both butyryl and acetyl cholinesterase inhibitor, may differentially affect different acetylcholinesterase subtypes	Delayed by food	40	1.4–2.6	<5	40	Hydrolysis by esterases and excreted. Duration of cholinesterase inhibition longer than plasma half-life. Nonlinear pharmacokinetics
Rivastigmine transdermal patch (Exelon)	(as above)	Not affected by food	100	8–16	3	40	Transdermal administration avoids extensive first-pass liver metabolism
Galantamine (Razadyne)	Competitive, reversible cholinesterase inhibitor, modulates nicotine receptors	Delayed by food	90	1	7	18	Via 2D6, 3A4

Note: Pharmacodynamic effects of some cholinesterase inhibitors are longer than their elimination half-lives. Drugs that inhibit or induce the cytochrome enzymes above might be expected to increase or decrease blood levels.

Cholinesterase inhibitors inhibit CNS acetylcholinesterase in the synaptic cleft, thus preventing the degradation of endogenously released acetylcholine (Table 55.4e–2). However, progressive presynaptic cholinergic neuron loss continues, so there is a progressively diminishing production of acetylcholine over time.

The three cholinesterase inhibitors that are currently marketed for the treatment of the cognitive symptoms of Alzheimer disease, and tacrine which is no longer marketed, can be grouped into two classes according to their structure and mode of inhibition: (1) reversible inhibitor tertiary and quaternary amines (i.e., tacrine, donepezil, or galantamine) and (2) pseudoirreversible inhibitor carbamates (i.e., rivastigmine). The irreversible organophosphate cholinesterase inhibitor metrifonate was clearly efficacious at higher doses but was not approved for marketing because of myasthenia and respiratory depression, possibly owing to its effects at the myoneural junction in muscles of respiration.

INDIVIDUAL CHOLINESTERASE INHIBITORS: CLINICAL STUDIES, DOSING, AND ADVERSE EFFECTS

For the most part, the several published multicenter trials of cholinesterase inhibitors were designed with the objective of obtaining marketing approval from the FDA. The protocols were fairly similar to each other, generally selecting outpatients with mild to moderate Alzheimer disease, usually with Mini-Mental State Examination (MMSE) scores between 10 and 26, inclusively. Patients in these trials were generally physically healthy, usually treated for 6 months or less, and more likely to be female, and they had a mean age of approximately 72 to 74 years, a decade lower than the median age of Alzheimer disease patients in the United States.

Tacrine

Tacrine is a noncompetitive reversible inhibitor of cholinesterase. It binds near the catalytically active site of the acetylcholinesterase molecule to inhibit enzyme activity. It has other actions as well, including blocking sodium and potassium channels and direct activity at muscarinic receptors. Statistically significant treatment effects for the 30 mg qid and 40 mg qid dosage groups were found on the ADAS-cog, a clinician’s interview-based impression of change rating, and activities of daily living in 3- and 6-month clinical trials. Tacrine will not be discussed further because it is no longer marketed. Additional information can be found in the previous editions of this book.

Donepezil

Donepezil is a long-acting, piperidine-based, highly selective, and reversible acetylcholinesterase inhibitor. Two phase III clinical trials provided pivotal evidence for the drug's FDA approval in late 1996. Additional randomized clinical trials include a trial of 6 months duration, a Scandinavian study of 12 months, a study of nursing home patients, a 6-month trial in which a large proportion of patients were more severely impaired than in previous trials, and an assessment of activities of daily living.

One non–industry-sponsored, randomized, placebo-controlled trial followed patients over several years, reporting very modest cognitive effects over 2 years but no significant effects on loss of function, nursing home placement, or health economic measures.

Pharmacokinetics. Oral bioavailability approaches 100%, with peak concentrations in 4 hours and linear pharmacokinetics. Donepezil is extensively bound to plasma proteins, including α_1-acid glycoproteins. The drug accumulates at a constant rate, reaching a steady state in approximately 2 weeks. It has a relatively slow clearance, with a long elimination half-life of 70 hours. It is both excreted unchanged in the urine and extensively metabolized by cytochrome P450 (CYP) 2D6 and 3A4 hepatic enzymes to active and inactive metabolites.

Drug Interactions. Inhibitors of CYP 3A4 and CYP 2D6 (such as ketoconazole [Nizoral] and quinidine [Quinaglute]) and inducers of CYP 3A4 and CYP 2D6 (such as phenytoin, carbamazepine, phenobarbital, and dexamethasone) could inhibit donepezil metabolism or increase its rate of elimination but may not be clinically significant in view of its high protein binding and very low therapeutic concentrations of 2 to 12 ng/mL.

Dosing. Donepezil is initiated at 5 mg per day and then increased to 10 mg per day after 4 to 6 weeks. Raising the dose earlier increases the risk for cholinergic adverse events. Five or 10 mg per day is an effective dose; 10 mg tends to be somewhat more effective than 5 mg when the various trials as a group are evaluated. The efficacy or appropriateness of higher doses has not been established.

A 23-mg formulation was marketed in 2010 intended for patients who are being maintained on 10 mg and for whom a higher dose is thought desirable. In a randomized, controlled trial, efficacy compared to patients who continued on 10 mg per day was not demonstrated.

Rivastigmine

Rivastigmine is a pseudoirreversible, selective acetylcholinesterase inhibitor and butyrylcholinesterase inhibitor. Four phase III randomized, placebo-controlled, 26-week-long clinical trials were completed of similar design but differing mainly in dosing methods. Two have been published, and the results of the other two have been included in secondary reports.

In the two published trials, doses were titrated weekly during the first 7 weeks to one of two dosage ranges, 1 to 4 mg per day or 6 to 12 mg per day, and dose decreases were not permitted, possibly contributing to lesser tolerability and seemingly more side effects during these stages of treatment.

A transdermal patch formulation was developed based on a placebo-controlled trial in mild to moderate Alzheimer disease comparing a 17.4-mg patch, 9.5-mg patch, and 6 mg of orally administered rivastigmine twice per day, and another trial using a 13.3-mg patch in severe Alzheimer disease.

Pharmacokinetics. Rivastigmine is well absorbed; very little binds to protein. Although the elimination half-life is less than 2 hours, enzyme inhibition lasts approximately 9 hours. Rivastigmine is not metabolized by the hepatic microsomal system. Rather, after binding to acetylcholinesterase, the carbamate portion of rivastigmine is slowly hydrolyzed (hence the “pseudoirreversibility”), conjugated to a sulfate, and excreted renally. Thus, its metabolism is essentially extrahepatic and unlikely to have significant pharmacokinetic interactions.

The pharmacokinetics of the transdermal patch shows a time to a maximum concentration of 8 to 16 hours and a 3-hour elimination half-life after the patch is removed.

Drug Interactions. Rivastigmine's metabolism does not depend on liver CYP enzymes; therefore, no drug interactions related to hepatic cytochromes have been observed.

Dosing. The starting dose of rivastigmine is 1.5 mg twice a day, taken with meals. If this dose is well tolerated after a minimum of 2 weeks of treatment, it may be increased to 3 mg twice a day. Subsequent increases to 4.5 mg and then 6 mg twice a day should be based on good tolerability of the current dose and may be considered after a minimum of 2 weeks of treatment. Higher daily doses are associated with better efficacy than lower doses. The initial transdermal patch is applied at 4.6 mg (5 cm^2) per day and then increased to one 9.5-mg (10-cm^2) patch per day after 4 weeks. The dosage level may be increased to a 13.3 (15-cm^2)-mg patch per day after a subsequent 4 weeks, and the usual maintenance doses may be 9.5-mg or 13.3-mg patch per day.

Galantamine

Galantamine, an alkaloid originally extracted from *Amaryllidaceae* (*Galanthus woronowii,* the Caucasian snowdrop) but now synthesized, is a reversible, competitive inhibitor of acetylcholinesterase with relatively less butyrylcholinesterase activity.

Because competitive inhibitors compete with acetylcholine at acetylcholinesterase-binding sites, their inhibition is, theoretically, dependent on intrasynaptic acetylcholine concentration in that they will be less likely to bind to sites in brain areas that have high acetylcholine levels. Another characteristic is allosteric modulation of nicotinic receptor sites, possibly enhancing cholinergic transmission by presynaptic nicotinic stimulation.

At least four large clinical trials involving more than 2,400 subjects have been published, generally showing efficacious doses between 8 mg twice a day and 16 mg twice a day, with few adverse effects at the low dose. Four milligrams twice a day was not an effective dose.

Pharmacokinetics. Galantamine is well absorbed and has approximately 90% bioavailability, little protein binding, and linear pharmacokinetics, with peak concentrations in approximately 1 hour and an elimination half-life of approximately 7 hours. It is metabolized by CYP 2D6 and 3A4, glucuronidated, and excreted in the urine. There is an approximately 25% decrease in clearance of galantamine in CYP 2D6 poor metabolizers.

Drug Interactions. Drugs that are potent inhibitors for CYP 2D6 or 3A4 may increase the availability and plasma levels of galantamine. Coadministration of paroxetine and ketoconazole increases the bioavailability of galantamine by 40% and 30%, respectively. Galantamine clearance is decreased by approximately 25% to 33% by concurrent administration of CYP 2D6 inhibitors, such as amitriptyline, fluoxetine, and quinidine; cimetidine increased bioavailability by approximately 16%. Galantamine itself does not inhibit CYP 3A4 or 2D6 and has little effect on the metabolism of other drugs.

Dosing. Initial dosing is 4 mg twice a day and should be raised to 8 mg twice a day after 2 to 4 weeks. For patients who are tolerating medication but not responding, the dose can be raised to 12 mg twice a day after another 4 weeks. The initial dose of the extended-release formulation is 8 mg per day and raised to 16 mg per day after 2 to 4 weeks, with the option to raise it to 24 mg per day.

Adverse Effects of Cholinesterase Inhibitors

The most common adverse events with cholinesterase inhibitors are cholinergically mediated and involve those related to cholinergic excess, including nausea, vomiting, diarrhea, dyspepsia, anorexia, fatigue, and weight loss. In addition, myalgia or muscle cramps occur in approximately 7% to 9% of patients, indicating direct myoneural effects (but do not seem to be associated with rivastigmine), which specifically inhibits only certain CNS acetylcholinesterase subtypes. The frequency of the cholinergic side effects generally is less than 15% and often no greater than placebo in clinical trials. In general, they tend to be mild and short lived, lasting less than 2 or 3 days, and occur around the time that dosage is increased. Medication dosage can usually be maintained or temporarily lowered and then raised. Fatigue also tends to occur, and occasionally there is a decrease in heart rate of 4 to 7 beats per minute, possibly due to enhanced vagal effects.

Direct reversible hepatotoxicity was associated only with tacrine, more commonly in women than men, and is the most common abnormal finding with this drug which is no longer marketed.

Contraindications to Cholinesterase Inhibitors

There are few absolute contraindications to cholinesterase inhibitors, and they relate to the unique chemical properties of each drug. Because of the actions of cholinesterase inhibitors, these drugs require caution when used in patients with significant asthma, significant chronic obstructive pulmonary disease, gastrointestinal ulcer disease, cardiac conduction defects, or clinically significant bradycardia. Appropriate considerations are involved in general anesthesia as well because they may prolong the effects of succinylcholine-type drugs.

Donepezil. The most common gastrointestinal adverse effects of donepezil include nausea, vomiting, diarrhea, and anorexia. In addition, some patients develop muscle cramps, headache, dizziness, syncope, flushing, insomnia, weakness, drowsiness, fatigue, agitation, and sleeplessness. Weight loss occurred at twice the rate of placebo in the nursing home study but not in outpatient trials. Adverse effects occurred at a higher rate when the titration from 5 to 10 mg was made in 1 week compared to 6 weeks.

Rivastigmine. Adverse effects with orally administered rivastigmine were primarily gastrointestinal and occurred in the high-dose (6 to 12 mg per day) group. They occurred mainly during dose escalation and led to withdrawal in one study in 23% of the high-dose group, 7% of the low-dose group, and 7% of the placebo group. Adverse effects that occurred in the higher-dose group were sweating, fatigue, asthenia, weight loss, malaise, dizziness, somnolence, nausea, vomiting, anorexia, and flatulence. In the maintenance phase, dizziness, nausea, vomiting, dyspepsia, and sinusitis occurred more in the 6 to 12 mg per day group than in the placebo group.

Adverse effects with the transdermal patch at the 17.4-mg dose were similar to 6 mg twice per day of oral rivastigmine, with the 13.3-mg dose somewhat less, and with the 9.5-mg dose were not significantly greater than placebo.

Galantamine. Galantamine's principal adverse effects were nausea, vomiting, diarrhea, anorexia, weight loss, abdominal pain, dizziness, and tremor. They were more frequent earlier in the course of treatment and during the dosage titration from 16 mg a day to 24 mg a day and higher. In one trial, the effective dosage of 16 mg per day was not associated with overall greater adverse events than experienced by the placebo-treated group.

Clinical Application and Treatment Implementation for Cholinesterase Inhibitors

The differential pharmacology of the cholinesterase inhibitors requires treatment considerations, such as once-per-day versus twice-per-day dosing, oral versus transdermal administration, and acetylcholinesterase inhibition versus butyrylcholinesterase inhibition. Answers are not known.

Donepezil and rivastigmine transdermal patches have been demonstrated to be effective in more severe patients as well as in outpatients with mild to moderate Alzheimer disease (MMSE scores between 10 and 26). Some experts believe that cognitive efficacy also is apparent in the more mildly and more severely cognitively impaired, but very few studies have been done on mild Alzheimer disease or MCI and did not show advantageous effects.

Duration of Treatment and Discontinuation

Placebo-controlled clinical trials with cholinesterase inhibitors have lasted only 6 months, with only a few exceptions. In some trials, when medication is discontinued, patients return within 3 to 6 weeks to the cognitive level of the placebo patients, indicating an overall symptomatic effect and that treatment efficacy is longer than 6 months. Three placebo-controlled trials suggest that, in some cases, efficacy could be longer than 1 year on cognitive and functional measures. A few analyses of databases or open-label extensions of clinical trials suggest that patients who tolerate and continue to take cholinesterase inhibitors over at least 1 year might experience a delay in nursing home placement compared to those who cannot tolerate or do not take them. However, these analyses are biased and probably subject to the “healthy patient effect,” whereby patients who are destined to have a milder course of illness or who have active caregivers are the ones who *can* take these medications, so that the apparent long-term effect compared to historical controls is illusory. These observational studies have not been supported by a recent, long-term, placebo-controlled trial.

Discontinuation of cholinesterase inhibitors occasionally has been associated with worsening cognition and occasional episodes of confusion in some patients. It is generally recommended that medication be tapered before discontinuing. In one trial in which donepezil was tapered and discontinued or continued, in moderate to severe outpatients who had been treated for at least 3 months, continuing donepezil was associated with slightly better cognitive and functional scores over the course of a year.

MEMANTINE: CLINICAL STUDIES, DOSING, AND ADVERSE EFFECTS

Overstimulation of NMDA receptors has been implicated as a causative mechanism in Alzheimer disease dementia. In preclinical studies, memantine, a moderate-affinity, uncompetitive NMDA receptor antagonist, protects against the effects of glutamate and calcium-mediated neurotoxicity. It has been available in Germany for the treatment of spasticity, Parkinson disease, and other neurologic disorders since 1982 and was approved by the European Union in

2002 and the United States in 2003 for treating moderately severe to severe Alzheimer disease.

Mechanism of Action

Memantine's action is hypothesized as being an open channel blocker without appreciable activity until increased glutamate levels trigger the receptor and cause the ion channel to open. It then enters the channel, occupying a site within it, preventing calcium influx and the depolarization and hyperactivation of the neuron. Because it is cleared from its site of action quickly, it might provide partial blocking of the channel, depending on intrasynaptic levels of glutamate. As glutamate increases, causing channels to open, memantine may block more, and as glutamate decreases, it may block less, allowing greater neuronal activity. In some respects, memantine can be viewed as a modulator of glutamatergic activity.

Clinical Studies in Moderate to Severe Alzheimer Disease

The effect of memantine on cognition generally has been mixed in clinical trials in moderate to severe Alzheimer disease (i.e., MMSE scores <15). Memantine (10 mg bid) was investigated for the treatment of moderate to severe Alzheimer disease in a 28-week, placebo-controlled trial of 252 patients. The decline of cognitive function was lessened in memantine patients compared to the deterioration observed in placebo.

Another 24-week, randomized, placebo-controlled trial of memantine in moderate to severe Alzheimer disease showed greater improvement in cognition, global assessment, and function compared to placebo. In this trial, memantine or placebo was administered to patients who had been maintained on stable doses of donepezil for at least 6 months. In fact, the average time on donepezil was approximately 2.5 years, with nearly 90% on it for more than 1 year before being randomized. Notably, the placebo-treated patients (i.e., patients who continued on donepezil throughout the 6 months of the trial) continued to decline at a rather rapid rate, suggesting that memantine substantially stabilized symptoms over this time, whereas any effect of the cholinesterase inhibitor may have been lost earlier over the disease course. Based on these two trials, memantine received marketing approval in the United States.

A third moderate to severe Alzheimer disease trial, however, which was similar in design to the other 6-month trials, failed to show significant effects for memantine compared to placebo.

A fourth moderate to severe Alzheimer disease trial failed to show that memantine was more effective than placebo over the course of a year when given to patients being maintained on donepezil. A fifth clinical trial, also in moderate to severe Alzheimer disease, did not find an overall clinical effect for memantine compared to placebo over the longer course of 2 years on average, again in patients maintained on cholinesterase inhibitors, while by contrast, it showed positive effects on function for vitamin E.

In a 12-week, randomized, placebo-controlled trial of memantine 10 mg per day in nursing home patients with Alzheimer disease or vascular dementia, memantine showed significant improvement over placebo in global assessment and activities of daily living.

Using the higher dose formulation, memantine, 28 mg, and intended for once-per-day administration showed efficacy over 24 weeks. The 28-mg-per-day dose has not been directly compared to the 10 mg bid dose in a single trial. The placebo-controlled trial of 28 mg per day did not show greater effects than the previous 10 mg bid placebo-controlled trials.

Clinical Studies in Mild to Moderate Alzheimer Disease

Two of three mild to moderate Alzheimer disease trials (i.e., MMSE scores from 10 to 23), one with patients taking cholinesterase inhibitors, did not show significant results, and a third showed significance only with one analysis. Based on these results, the FDA did not approve memantine for mild Alzheimer disease.

Pharmacokinetics

Memantine absorption is not affected by food intake; bioavailability is 100%. Plasma protein binding is 45%, and peak plasma concentrations occur 3 to 7 hours after oral intake. It is widely distributed and rapidly diffuses across the blood–brain barrier. The majority of the parent compound is excreted unchanged in the urine, in part by tubular secretion. There is minimum hepatic metabolism; the elimination half-life is 60 to 80 hours.

The 28-mg formulation, an extended-release capsule, shows a C_{max} and 24-hour Area under the Curve (AUC) that is 48% and 33% higher than the original memantine formulation, with an elimination half-life from 60 to 80 hours. The extended-release formulation is also available in combination with donepezil.

Drug Interactions

Interactions with memantine are few. There are potential interactions with hydrochlorothiazide, resulting in a lower plasma level of the diuretic or a potentially reduced effect. There are no known interactions with cholinesterase inhibitors. Drugs that alkalinize urine would reduce the renal clearance of memantine.

Dosing

Dosing is fairly straightforward, with titration to 10 mg bid over the course of 3 weeks, starting at 5 mg qd and increasing the daily dose by 5 mg each week; or with 7-mg capsules qd, and increasing by 7 mg qd each week to a dose of 29 mg qd.

Adverse Events

Interestingly, agitation occurred less often in memantine treatment groups than in placebo groups. In the memantine add-on trial, confusion, generally rated as mild, occurred four times more frequently in the memantine group, and headache twice as frequently. Of note, gastrointestinal symptoms were less frequent, with diarrhea or fecal incontinence occurring half as frequently in the memantine group, suggesting that the actions of memantine may mitigate some of the cholinergic effects of donepezil.

Clinical Application and Treatment

Memantine is indicated for moderate to severe dementia of the Alzheimer disease type, which generally corresponds to patients with MMSE scores of 14 or less. It generally can be considered as initial treatment for this group if patients have not been treated previously. If they have, then memantine can be added to a cholinesterase inhibitor as well. Because the clinical trials that showed efficacy were no longer than 6 months, treatment duration is unclear, and issues are similar to those of the cholinesterase inhibitors. Whether discontinuation is associated with worsening symptoms is not known.

Although memantine is commonly used with or without a cholinesterase inhibitor in mild Alzheimer disease, clinical trials assessing efficacy in mild to moderate Alzheimer disease have not demonstrated cognitive efficacy for memantine. This is due to a lack of efficacy observed in the mild subgroup of patients in these trials, and memantine is not FDA approved for mild Alzheimer disease. Nevertheless, it is commonly used in mild Alzheimer disease, with nearly half of mild Alzheimer disease patients in observational research studies receiving it.

OTHER MEDICATIONS AND APPROACHES TO ALZHEIMER DISEASE AND COGNITIVE ENHANCEMENT

Although cholinesterase inhibitors have been the most studied class of medications for Alzheimer disease, a broad range of other drugs and supplements are available for prescribing in some countries or are undergoing clinical trials. Some of these may be approved for marketing in the United States, but for other indications. These approaches might improve symptoms or slow neurodegenerative processes, or both.

Atypical inflammatory responses, the production of oxidizing free radicals, and the production from amyloid precursor protein of insoluble and possibly toxic β-amyloid peptide fragments are part of the neurodegenerative process. Therefore, anti-inflammatories and antioxidants might have a role in the treatment of progressive dementias. The neurotrophic and cholinergic properties of estrogens were hypothesized to be useful in women.

Huperzine A

Huperzine A is a plant extract that has selective acetylcholinesterase inhibition. It is sold as a food supplement and is a traditional Chinese treatment. A phase II trial failed to demonstrate efficacy at a lower dose of 200 mcg bid, but with a suggestion of a cognitive effect at 400 mcg bid.

Monoamine Oxidase Type B Inhibitors

Some positive effects have been reported with selegiline, a monoamine oxidase (MAO) inhibitor that relatively selectively inhibits MAO type B at a 5- to 10-mg daily dose. At this dose, its overall effect may be to increase CNS levels of dopamine and trace neurotransmitters, such as phenylethylamine, without affecting norepinephrine levels. Selegiline is marketed for the treatment of Parkinson disease, for which it has demonstrated effects in maintaining motor function and, in some Eastern European countries, as a cognitive enhancer.

From a different perspective, selegiline and other MAO type B inhibitors may have neuroprotective potential. Elevated levels of MAO type B in the brains of Alzheimer disease patients might lead to elevated levels of neurotoxins, such as 6-hydroxydopamine, quinones, and free radicals. It has also been postulated that exposure to substances in the environment could lead to neurotoxic products (via oxidative biotransformation). In either case, inhibition of MAO on a chronic basis could theoretically retard the progression of the illness based on antitoxic mechanisms. Also, selegiline may have neuronal “rescue” effects based on neurotrophic-like properties not involving MAO inhibition. It is notable that rodents and dogs treated with selegiline have increased survival. Selegiline is also marketed in the United States as an FDA-approved veterinary medicine for “canine cognitive dysfunction.”

A 12-month placebo-controlled trial of transdermal selegiline in patients with milder Alzheimer disease revealed no significant effects overall. Oral selegiline, 5 mg twice a day, along with and separately from vitamin E, 1,000 IU twice a day, has been associated with prolonged maintenance of activities of daily living and avoidance of nursing home placement in moderately to severely impaired Alzheimer disease patients, but with no improvement in cognitive function. An adequate efficacy trial has yet to be completed in Alzheimer disease.

Another recent, 12-month, phase II, placebo-controlled trial of the MAO-I, RO4602522 (EVT 302), did not show efficacy in 495 patients with moderate Alzheimer disease.

Ladostigil is a derivative of rasagiline and rivastigmine. It acts as a cholinesterase inhibitor and MAO-I; it has antioxidant properties and modulates the processing of amyloid precursor protein. It was assessed in a mild to moderate Alzheimer disease trial and in a phase II trial in MCI. In both trials, ladostigil missed its primary endpoints. In sum, there is little evidence for the efficacy of MAO type B inhibitors.

Ergoloid Mesylates

Ergoloid mesylate was a commonly used putative cognitive-enhancing drug until the advent of the cholinesterase inhibitors and is no longer marketed in the United States. It was used primarily for patients with dementia, age-associated cognitive symptoms, or memory complaints. The agent has mixed and complex actions on central α-adrenergic, dopaminergic, and serotonergic receptors.

Nootropics

The term *nootropic* is derived from the Greek *noos* (mind) and *troepin* (forward) and refers to a drug class with diverse actions structurally related to piracetam. They are pyrrolidine derivatives of γ-aminobutyric acid (GABA), although they do not appear to have GABA-like effects and are postulated to have a neuroprotective effect on the CNS against hypoxia, electroconvulsive treatment, and drug intoxication. They also may enhance the CNS microcirculation by reducing platelet activity and adherence of red blood cells to vessel walls and may stimulate central cholinergic activity. They include piracetam, oxiracetam, pramiracetam, and aniracetam. They may improve memory and learning, but an antidementia mechanism has not been established.

Clinical trials of nootropics in Alzheimer disease have shown mixed results with piracetam in the treatment of dementia in older adults. Pramiracetam and oxiracetam have been evaluated in large-scale multicenter studies with no sufficiently significant clinical effects in dementia or in MCI. Nootropics, however, are marketed for the treatment of dementia and cognitive impairment in countries other than the United States. There is some evidence for efficacy in attention-deficit disorder.

Ginkgo Biloba

The ability of an extract from the leaves of *Ginkgo biloba* to improve cognitive function in Alzheimer disease patients is the subject of ongoing work. Preclinical evidence suggests that certain flavonoid components in *Ginkgo* might have neuroprotective effects, including scavenging of oxygen free radicals; protection of membranes against lipid peroxidation; inhibition of β-amyloid formation, aggregation, and toxicity; and antiapoptotic effects, and may increase hippocampal muscarinic receptors and enhance choline uptake.

A preparation (EGb 761) is approved in Germany for "disturbances of cerebral function related to dementia syndromes," supported by various clinical studies. However, a clear role for *Gingko,* as a symptomatic agent or in the prevention of Alzheimer disease has not been determined. One 52-week placebo-controlled, double-blind trial of 309 patients with Alzheimer disease or vascular dementia demonstrated that 120 mg per day of a standardized *Ginkgo* extract (EGb 761) conferred a statistically significant improvement on the ADAS-cog scores compared to placebo. A 6-month placebo-controlled trial of 120 and 240 mg per day of EGb 761 for mild to moderate Alzheimer disease, however, did not show efficacy. A Cochrane meta-analysis did not support the advantageous effects of

Ginkgo biloba extract for Alzheimer disease or as a cognitive enhancer. A randomized, placebo-controlled trial (the Gingko Evaluation of Memory Study [GEMS]) funded by the National Center for Complementary and Alternative Medication evaluated *Ginkgo biloba* EGb 761 extract, 240 mg per day, in delaying the onset of Alzheimer disease or MCI in 3,072 subjects aged 75 years and older who were followed over 5 years and found no effect. Another prevention study in 200 subjects 85 years or older, also sponsored by the National Center for Complementary and Alternative Medication, did not find an effect for 240 mg per day of EGb 761 in delaying progression to MCI. Finally, a multicenter prevention trial in France involving 2,854 patients followed for 5 years did not show a positive effect for EGb 761 for delaying dementia or improving cognition.

Based on these studies, there is little or no evidence to recommend *Ginkgo biloba* for the treatment of Alzheimer disease or vascular dementia. Studies in normal older adult subjects have been inconsistent, presenting a confusing picture for its use, perhaps partly owing to variations in dose, duration, and methodologic issues such as lack of blinding.

Vitamin E

The antioxidant effects of vitamin E (DL-α-tocopherol) might have an impact on reducing clinical progression. In the prototypical antioxidant trial, vitamin E (1,000 IU twice a day) and selegiline (5 mg twice a day), each given alone to moderately impaired patients with Alzheimer disease, delayed the time until patients required nursing home placement died or lost activities of daily living. Overall, the delayed time to these end points was approximately 7 months compared to the placebo. There were no effects on cognition in this group of patients, who were more severely impaired than in other studies. Adverse effects included falls and syncope in selegiline patients (9% and 10%, respectively), α-tocopherol patients (14% and 7%, respectively), and the combination (22% and 16%, respectively).

A multicenter trial in amnestic MCI patients reported no significant delay in conversion to Alzheimer disease or in cognitive effects with α-tocopherol over 3 years of treatment. The outcomes of the previous moderate to severe Alzheimer disease trial were supported by a trial comparing vitamin E with memantine and placebo over 2 years on average and showing improved function with vitamin E and not with memantine.

Taken together, considering the absence of cognitive efficacy and the potential risks for treatment, vitamin E cannot be recommended as a treatment.

B Vitamins and Homocysteine Reduction

Elevated levels of homocysteine are a risk factor for cardiovascular disease, vascular dementia, and Alzheimer disease. Plasma concentrations rise when homocysteine's metabolism to methionine or cysteine is impaired, which may occur under a number of circumstances, including natural aging. Increased blood levels of homocysteine are associated with damage to vascular endothelial cells through lipid peroxidation and release of endothelium-derived relaxing factor and may increase the risk of vascular thrombosis. More relevant to Alzheimer disease, homocysteine potentiates the neurotoxic effects of β-amyloid peptides in vitro. Homocysteine plasma levels can be reduced by as much as 30% using regimens of B vitamins (e.g., B_{12} 1 mg per day, B_6 25 mg per day, and folic acid 5 mg per day). A placebo-controlled clinical trial of these vitamins over 18 months in patients with mild to moderate Alzheimer disease confirmed that a substantial reduction in homocysteine could be achieved but did not show cognitive or functional effects compared to placebo.

HMG-CoA Reductase Inhibitors

Epidemiologic evidence suggests that cholesterol lowering and the use of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors ("statins") may impact the development or progression of Alzheimer disease, possibly because cholesterol levels modulate the enzymatic processing of amyloid precursor protein and consequently the production of β-amyloid, a main component of neuritic plaques in the Alzheimer disease brain. Furthermore, cholesterol-fed rabbits demonstrate increased β-amyloid in the brain, and hypercholesterolemia induced by a high-cholesterol diet results in increased levels of β-amyloid in the CNS. Statin administration in vitro reduces intra- and extracellular β-amyloid levels in neuronal cultures.

Observational studies of patient records demonstrated a 60% to 73% lower prevalence of Alzheimer disease in lovastatin (Mevacor)- or pravastatin (Pravachol)-treated patients and a markedly reduced risk for Alzheimer disease as assessed in an analysis of a clinical database.

Clinical trials, however, generally have not supported the use of statins for Alzheimer disease. A randomized, placebo-controlled trial of pravastatin (the PROSPER study) in 5,804 subjects aged 70 to 82 years with risk factors for vascular disease reported favorable cardiovascular outcomes but no significant effect on cognitive function or disability during an approximately 3-year follow-up period. In a randomized, placebo-controlled trial of the effect of simvastatin (Zocor) on cardiovascular outcomes in a subgroup of 5,806 patients aged 70 or more years, there was no significant difference in the proportion of patients with cognitive impairment or in the incidence of dementia over the average 5-year follow-up period.

A small-scale trial of atorvastatin (Lipitor) indicated some positive cognitive effects. Two larger placebo-controlled trials, one with simvastatin and another with atorvastatin, including 400 and 641 patients, respectively, treated over 18 months, did not show positive effects for the drugs in symptoms or in slowing the clinical decline of Alzheimer disease patients.

More recently, case reports have brought attention to patient reports of the possible adverse effect of statin use on cognition. However, a recent systematic review and meta-analysis of observational studies appeared to confirm the absence of a neurocognitive risk associated with statin treatment and suggested a potential favorable role of statins in reducing the risk of dementia. Randomized clinical trials with an ad hoc design are needed to explore this potential neuroprotective effect. However, at this time, these drugs should not be considered useful for preventing or treating Alzheimer disease.

Docosahexaenoic Acid

A reduced risk of Alzheimer disease associated with fish consumption in epidemiologic studies is also associated with omega-3 fatty acids. Docosahexaenoic acid (DHA) is an omega-3 fatty acid found in fish oil, a component of neural membrane phospholipids. Several animal studies show DHA to have antiamyloid, antioxidant, and neuroprotective mechanisms. A carefully conducted multicenter, randomized, placebo-controlled trial of DHA in patients with mild to moderate Alzheimer disease did not show efficacy for DHA.

Souvenaid

Souvenaid (Nutricia N.V.) is marketed outside the United States as a medical food. It contains uridine, choline, phospholipids, eicosapentaenoic acid, DHA, selenium, and vitamins E, C, B_{12}, and B_6; folic acid. The rationale is that these are precursors and cofactors for the development of neuronal membranes and are intended to support the formation of synapses. This represents both a structure/function food supplement claim and a medical food claim. Clinical trials in Alzheimer disease, however, have not been supportive of a clinical or functional effect.

Axona

A particular liquid formulation of medium-chain fatty triglycerides composed of glycerin and caprylic acid (AC-1204 or Axona) is intended to create chronic ketosis in an effort to enhance mitochondrial metabolism. A rationale is that a reduction in cerebral glucose uptake and utilization is observed in Alzheimer disease. Therefore, the AC-1204 formulation is intended to improve cellular metabolism by providing an alternative energy substrate to glucose. Caprylic acid is metabolized into the ketone bodies acetoacetic acid and β-hydroxybutyric acid, which in turn are converted to acetyl-CoA and energy by the tricarboxylic acid (TCA or Krebs) cycle.

The formulation was initially marketed as a medical food for Alzheimer disease and then withdrawn by the FDA because of absent clinical trials efficacy evidence and claims. A subsequent phase III trial to assess potential efficacy for its use as a drug rather than as a medical food also failed.

UNPROVEN AND UNSAFE MEDICATIONS TO SLOW CLINICAL PROGRESSION OR DELAY ONSET OF ALZHEIMER DISEASE

Anti-inflammatories

Markers of inflammation in the brains of Alzheimer disease patients suggest a potential therapeutic benefit of anti-inflammatories. Epidemiologic studies with nonsteroidal anti-inflammatory drugs (NSAIDs) indicate that these agents may be potentially effective for reducing the incidence or delaying the onset of Alzheimer disease.

Nonsteroidal Anti-Inflammatory Drugs and Alzheimer Disease. For example, (1) patients with rheumatoid arthritis who receive chronic anti-inflammatory treatment have a reduced risk for Alzheimer disease compared to controls without rheumatoid arthritis, (2) twins who used anti-inflammatory medications had a lesser risk for Alzheimer disease than did their co-twins, and (3) the risk of Alzheimer disease was reduced in cohorts of people using anti-inflammatories in middle age years before the typical onset of Alzheimer disease.

A placebo-controlled trial of indomethacin (Indocin) initially supported a potential role for at least NSAIDs. Subsequent randomized, placebo-controlled trials of NSAIDs in Alzheimer disease patients have failed to show a clinical benefit. Moreover, 1-year-long, placebo-controlled trials of low-dose prednisone (10 mg) or NSAIDs by the National Institute of Aging Alzheimer's Disease Cooperative Study and long-term trials of celecoxib (Celebrex) and rofecoxib (Vioxx) did not show advantageous effects.

To investigate the effect of NSAIDs in delaying the onset of Alzheimer disease, an ongoing multisite trial (the Alzheimer's Disease Anti-Inflammatory Prevention Trial) randomized approximately 2,528 patients aged 70 years or older with a family history of dementia to naproxen (Aleve), celecoxib, or placebo, and followed them for 5 to 7 years before the trial was ended early due to cardiovascular toxicity concerns. Results, however, indicated nontherapeutic and cognitively toxic effects with increased risk for Alzheimer disease with both treatments.

In view of the negative clinical trials with NSAIDs and considering their frequent adverse effects, including gastrointestinal bleeding, especially with long-term use, NSAIDs cannot be recommended for the prophylaxis or treatment of Alzheimer disease.

Estrogens

Preclinical evidence amply demonstrates that estrogens improve cognitive function through cholinergic neuroprotective and neurotrophic effects. For example, estradiol (Estrace) replacement increases choline acetyltransferase and acetylcholine after ovariectomy and enhances learning in ovariectomized rats. Clinical evidence of a possible effect of estrogen replacement therapy (ERT) has included observations of an inverse relationship between ERT and death certificate diagnoses of dementia, several case-control and cohort studies in which 40% to 50% reductions in the risk for developing Alzheimer disease were reported, and several smaller clinical reports suggesting that estradiol, estrone (Estrol), or conjugated equine estrogens (CEE, Premarin) enhance cognitive function in Alzheimer disease.

Acute adverse events with ERT are frequent and generally dose dependent and include endometrial hyperplasia, uterine bleeding (when taken with a progestin), breast tenderness, nausea, and venous thrombosis, among others. Because of the enhanced risk for endometrial cancer when estrogens are given to women with intact uteri, administration of progestins with estrogens has been recommended for women with intact uteri.

During the last few years, a number of clinical trials have been carried out, and except for one very small trial using transdermal estradiol, results with CEE (without a progestin) did not substantiate their efficacy. A 20-week-long and a 1-year-long trial of CEE in hysterectomized women were negative. Indeed, there was a trend in women receiving hormone replacement to worsen cognitively and—although a relatively small sample size—have greater adverse events, including a few instances of deep vein thrombosis.

Without evidence for efficacy, then safety is of great concern. The Women’s Health Initiative trial followed a large number of women randomly assigned to hormone replacement therapy (CEE with or without the progestin medroxyprogesterone [Provera or PremPro when combined with CEE]) or placebo to assess potential cardioprotective effects of the hormone replacement. In 2002, the arm of the trial that included combination treatment was halted because of a substantial increase in cardiovascular adverse effects. The results of the cognitive outcomes in 4,532 women in the subgroup older than 65 years were reported in 2003, finding that the CEE/medroxyprogesterone-treated women had an increased risk for developing dementia. In 2004, the arm of the trial that included CEE treatment alone also was halted for lack of effect and increased strokes with estrogens. CEE alone was associated with an increased incidence of dementia and worse cognition over the approximately 5-year follow-up period.

It is possible but not at all proven that estrogen treatment in midlife around menopause could be neurotrophic and preventative of the onset of Alzheimer disease, but beyond epidemiologic studies, evidence is lacking. The lack of any salutary cognitive effects, combined with the substantial cardiovascular, stroke, and breast cancer risk over the long term, strongly suggests that there is no role for the use of combined estrogen/progestin or CEE-alone intervention in women over 65 years of age.

ADJUNCTIVE AND COMBINATION THERAPY

It is not known whether combining medications such as cholinesterase inhibitors with other drugs or vitamins confers added efficacy. There have only been pilot studies comparing combinations of cholinesterase inhibitors with such drugs as selegiline, suggesting only their feasibility and not efficacy. The combination of selegiline and vitamin E did not confer any added benefits over either alone in one study and was associated with greater adverse effects.

The combination of a cholinesterase inhibitor with memantine is another example of the potential use of combined therapy. Although such issues as what drug to use first or whether to start both simultaneously have not been worked out, nor is there evidence that each drug separately has an effect that the other does not, it appears that the medications can be used together safely.

A recent network meta-analysis of memantine plus donepezil showed superior outcomes for cognition, global assessment, daily activities, and neuropsychiatric symptoms, but lower acceptability than monotherapy and placebo.

TREATMENT OF MILD COGNITIVE IMPAIRMENT

Operational criteria for MCI are generally taken to include a subjective cognitive (memory) complaint; MMSE within normal limits; neuropsychological tests for memory greater than 1.5 standard deviations below age-appropriate norms; activities of daily living within normal limits; and Clinical Dementia Rating Scale score of 0.5, indicating no dementia. Criteria for MCI due to Alzheimer disease and used for clinical trials, however, are slightly different, requiring as well progressive worsening and a delayed memory deficit on the Logical Memory II delayed recall below 9 in most cases.

In research clinics, a diagnosis of “amnestic mild cognitive impairment” or “mild cognitive impairment of the amnestic type,” marked by predominant memory impairment, implies a conversion rate to Alzheimer disease of about 12% to 15% per year. However, MCI is not necessarily a predementia stage of Alzheimer disease because many people who fulfill the criteria do not progress to dementia, and some improve to not being cognitively impaired. The meaning of MCI is further confounded as it is also viewed as a transitional state on the road to the development of Alzheimer disease, as an “at-risk” state with an increased likelihood for dementia over a specified time, and as the very early diagnosis of Alzheimer disease before the full dementia syndrome is recognized.

Although criteria for MCI can be defined by consensus, the diagnosis as variously used suffers from vagueness in conceptualization, with the condition overlapping with Alzheimer disease. The application of MCI criteria seems to vary, however, and the diagnosis does not necessarily predict the onset of Alzheimer disease. For example, although all MCI trials nominally used the Mayo Clinic criteria for MCI, when the criteria from three clinical trials were applied to the same clinic cohort, differing prevalences were found from 17% to 51%. For clinical diagnostic purposes, MCI has broadly been defined as mild neurocognitive impairment in DSM-5.

MCI has been a therapeutic target for several clinical trials of cholinesterase inhibitor medications marketed for Alzheimer disease. These trials have ranged from 2 to 4 years in duration. None showed positive effects for the cholinesterase inhibitor in delaying time to dementia onset or improving cognitive scores beyond 6 to 12 months. Given the vagaries of the definition of MCI, that many people with MCI will not progress, the adverse effects of the medications, and the lack of efficacy in the trials, the use of cholinesterase inhibitors for people with MCI cannot be recommended.

A development for clinical research and trials is to define MCI “due to Alzheimer’s disease” or the equivalent “prodromal Alzheimer’s disease” by the above clinical and cognitive criteria but to also require a positive amyloid-β PET scan or low amyloid-β CSF levels to enhance the likelihood that the research participant will progress to Alzheimer disease.

TREATMENT OF VASCULAR DEMENTIA

Although a range of treatments has been proposed for the cognitive deficits of ischemic vascular dementia, more recently conducted trials using particular research criteria for vascular dementia have yielded the best efficacy evidence. Six-month trials of the cholinesterase inhibitors donepezil and galantamine have generally demonstrated very modest cognitive efficacy similar to that shown in Alzheimer disease but often without evidence of global improvement or improvement in activities of daily living. Similarly, two 6-month multicenter trials of memantine also tended to show improvements in cognition. These trials relied on a cognitive battery designed for patients with Alzheimer disease.

Overall there is insufficient evidence for the efficacy of cholinesterase inhibitors or memantine in vascular dementia. One limitation is that vascular dementia is a heterogeneous condition that is difficult to define clinically and often overlaps with Alzheimer disease. These drugs are not approved for use in vascular dementia. The results of the trials demonstrate that cognitively enhancing medications might be useful in other conditions besides Alzheimer disease.

TREATMENT OF PARKINSON DISEASE DEMENTIA

Patients with Parkinson disease have an increased risk for dementia, and about 25% may develop dementia after the onset of the illness. The dementia, occurring after the onset of parkinsonian motor symptoms, can be characterized by a particular pattern of impairments in executive function, memory, and attention that is different from other dementias such as Alzheimer disease.

From an FDA perspective, however, a diagnosis of Parkinson disease dementia is made in patients in whom “a progressive dementia syndrome occurs at least 2 years after a diagnosis of Parkinson’s disease” in the absence of other causes of the dementia. This definition came about as a result of the FDA approving the cholinesterase inhibitor rivastigmine for “mild to moderate dementia associated with Parkinson’s disease.” Thus, rivastigmine used in the same dosing range as with Alzheimer disease is the only drug indicated for treating the dementia.

β-Amyloid–Based Interventions

Aducanumab is an amyloid-β–directed antibody, which was approved by the FDA in 2021 for the treatment of Alzheimer disease through their Accelerated Approval pathway. This pathway allows for the approval of treatments for serious or life-threatening illnesses where there is the expectation of clinical benefit despite some uncertainty and when the therapy may provide an advantage over existing treatments. This approval was based on a surrogate endpoint of the reduction of β-amyloid plaque, as there was conflicting data in two phase III clinical trials surrounding the reduction of clinical decline. The treatment will now need a postapproval trial demonstrating clinical benefit. After an initial titration, aducanumab is administered as an intravenous infusion every 4 weeks at a maintenance dose of 10 mg/kg. This is the first disease-modifying therapy approved by the FDA for Alzheimer disease and is the first medication approved by the FDA for Alzheimer disease since 2003. Intravenous lecanemab (Leqembi) was also granted accelerated approval for the treatment of Alzheimer disease in January 2023, after a phase 3 trial demonstrated a reduction in brain amyloid levels and less cognitive decline. It was granted a traditional approval after a confirmatory trial verified clinical benefit. It is recommended that it should be used in patients with mild cognitive impairment or mild dementia, the population in which treatment was studied in clinical trials. Due to concerns about developing amyloid-related imaging abnormalities or ARIA, a type of brain swelling or bleeding brain, imaging monitoring is recommended for both these agents.

Other drugs with a broad range of mechanisms are in development. They include β- and γ-secretase inhibitors that prevent the cleavage of amyloid precursor protein into insoluble β-amyloid; vaccines such as synthetic β-amyloid in order to generate β-amyloid antibodies; the use of other manufactured antibodies against β-amyloid blocking the receptor for advanced glycation endproducts (RAGE) from binding amyloid; preventing amyloid fibril formation; and a range of other “antiamyloid” approaches.

Moreover, there is a new focus on the development of neuroprotective medications or drugs that might cause neurogenesis or enhance plasticity; and drugs and antibodies directed against tau-protein targets. Research and development efforts, of course, continue.

FUTURE DIRECTIONS

Current pharmacologic treatment options for improving cognition in Alzheimer disease include cholinesterase inhibitors and memantine. Other available drugs, food supplements, and vitamins, including anti-inflammatories, available estrogens, B-complex vitamins, vitamin E, medium-chain fatty acids, and *Ginkgo biloba* extract, have not been proven efficacious. Some show considerable toxicity in clinical trials and cannot be recommended for use.

Ideally, it would be best to treat Alzheimer disease early before the onset of dementia; however, there are no current drugs for this, and cholinesterase inhibitors have been demonstrated to be ineffective in this regard.

Although no currently available antidementia treatment has shown dramatic effects in improving the cognitive impairments of Alzheimer disease, the improvements nonetheless may be clinically meaningful for some people. Therapeutic results are usually modest, affecting a minority of patients. Cholinesterase inhibitors are the best proven efficacious symptomatic treatments for Alzheimer disease. Patients assessed and treated in clinical trials, however, were usually outpatients with mild to moderately severe dementia and few concomitant medical illnesses. Duration of effect beyond 6 months to 1 year (2 years in one trial) and long-term safety is not known.

The efficacy of these drugs for other cognitive disorders remains to be established, although the FDA has approved rivastigmine for Parkinson disease dementia. Disease-Modifying Therapy and Prevention trials are ongoing. Future treatments with greater efficacy in Alzheimer disease and for cognitive enhancement in older adult patients will be dependent on a greater understanding of possible neurobiologic underpinnings of cognition, brain imaging, and the various neurocognitive disorders. The challenge will be to develop treatments that have a reasonable benefit-to-risk ratio.

ACKNOWLEDGMENTS

This chapter represents an update and revision of previous chapters in this series, most recently by Lon S. Schneider, M.D., from the last edition. The author is indebted to Dr. Schneider for his work and retains much of his prose in this current edition.

55.4f Electroconvulsive Therapy and Neurostimulation Treatments

Mustafa M. Husain, M.D., Tarek K. Rajji, M.D., F.R.C.P.C., and Robert Garrett, M.D.

Chapters 34.20a and 34.20b comprehensively detail the application of electroconvulsive therapy (ECT) and other neurostimulation therapies, respectively. This particular section applies to the utility of ECT and other neurostimulation therapies in a geriatric population.

BRIEF HISTORY AND BACKGROUND

Convulsive therapy was introduced in the early part of the 20th century by Ladislas von Meduna as a treatment for severe catatonia in dementia praecox by use of camphor oil injections. In the late 1930s, Ugo Cerletti and Luigi Bini refined convulsive therapy by using electrical stimulation to induce therapeutic convulsions, and this formed the precursor of modern-day ECT. Due to its broad applications and, at times, misapplications to a variety of psychiatric diseases in the 1940s, as well as its associated cognitive adverse effects, ECT received substantial criticism from both inside and outside the psychiatric community. These critiques of ECT resulted in its limited use, but they also procured its scientific and systematic development as a clinically beneficial and safe treatment modality.

A report of older adult patients who received Medicare between the years of 1987 and 1992 found that the rate of ECT use increased each successive year. For example, from 1987 to 1992, the number of patients treated with ECT increased from 12,000 to 15,560. In the state of Texas, annual reports of ECT use showed that in 2007 a total of 1,772 patients received ECT, and of those, 22% were over the age of 65, with the oldest patient treated at age 94.

Unfortunately, the use of ECT has been declining in the United States. A study of general hospital stays for ECT for the period from 1993 to 2009 showed that the average number of stays declined from 12.6 to 7.2 per 100,000 adult U.S. residents. The percentage of general hospitals conducting ECT also decreased—from 15.8% to 10.6%. The decline for geriatric patients (over 65 years old) was significant. The number of inpatient stays for this population declined from 41.2 per 100,000 U.S. residents in 1995 to 12.3 per 100,000 in 2009. While this data may not reflect all ECT conducted in the United States, the trend is concerning, especially in light of the proven efficacy of ECT. This occurs in the backdrop of a rapidly growing U.S. population of adults 65 years old and older. In 2020 there were approximately 56.1 million in this age group, but this is expected to grow to 80.8 million in 2040.

In a survey of 306 geriatric psychiatrists in the United Kingdom, the majority felt that ECT is a well-tolerated and beneficial treatment for geriatric patients with severe psychiatric disorders, even those patients who are 80 years of age and older. On the other hand, a 2004 survey of practitioners in the Netherlands suggested that there is hesitation to utilize ECT in older adult patients as a first, second, or even as third option. While 84% of the 152 psychiatrists noted that the use of ECT should be broadened in older adult patients, approximately 54% agreed that it should be a first- or second-line treatment option. Equally important, only 15.1% and 13.9% indicated ECT as a first-line treatment for major depression with psychotic features or severe suicidal risk, respectively. Collectively, these surveys suggest that the practice of ECT is influenced by practitioner opinion and experience and that usage estimates vary per country.

PRECLINICAL STUDIES

Preclinical studies have shown that with ECT stimulation, there is increased hippocampal expression in the dentate gyrus of neurotropic and transcription factors, including the neurotropic factors: brain-derived neurotrophic factor (BDNF), vascular endothelial growth factor (VEGF), and fibroblast growth factor (FGF) and transcription factors, including c-Fos (which plays an important role in signal transduction, cell proliferation, and differentiation) and the arachidonic acid pathway (COX 2). There are cell proliferation and neurotropic effects of ECT also in the prefrontal cortex, amygdala, and hypothalamus. After several stimulations, there is a release of even more neuropeptide factors, including neuropeptide Y, thyrotropin-releasing hormone, and an increase in nerve growth factors. Chronic ECT works by changing gene expression. Thus, relapse after ECT is thought to be due to disrupted realteration of genes. Chronic ECT also helps strengthen second messenger systems. With the emergence of treatment-resistant depression, defined as depression that does not improve after adequate and substantial antidepressant treatment, ECT has found a new role in antidepressant algorithms.

CLINICAL INDICATIONS

ECT is one of the most effective somatic therapy for neuropsychiatric disorders. In the older adult, it is often the treatment of choice for severe depression. Depressed geriatric patients are especially at high risk for sequela of depression, including psychotic symptoms, malnutrition, weight loss, and inactivity. As a result, ECT is commonly employed in geriatric depression with the added benefit that it is relatively safe and well-tolerated compared to medications. ECT often becomes the first-line treatment recommendation for patients who are acutely suicidal, psychotic, or present with severe melancholia. Recent research studies suggest that among patients receiving ECT, older age is associated with rapid response and remission. The PRIDE 1 (Prolonging Remission in Depressed Elderly) study of ECT for geriatric depression included 240 patients in the acute phase. In this study, the response rate was 70%, the remission rate was 62%, and the mean time to remission was 2.5 weeks.

Relapse after the index course of ECT is of major clinical significance; it is thought to be due to disrupted realteration of genes. With the emergence of treatment-resistant depression, defined as depression that does not improve after adequate and substantial antidepressant treatment, ECT has found a new role in antidepressant algorithms.

Mrs. C is a 70-year-old Caucasian woman with a 2-year history of severe recurrent major depression and a three-and-a-half-year history of Parkinson disease, initially treated with Sinemet. She was referred by her outpatient psychiatrist for an ECT consultation. She was taking Remeron 45 mg nightly and Wellbutrin XL 150 mg daily. She had been switched from Sinemet to Ropinirole, which due to lack of effect, was discontinued in November 2014.

Prominent symptoms included: decreased self-care, decreased appetite with 20-pound weight loss within a year, decreased sleep, marked social withdrawal, spending 22 hours a day in bed, and decreased mobility. She was, per family, “alive, but not living,” and “her smile was not there anymore.” She stopped watching TV and preferred keeping the shades down. Mrs. C’s Parkinson disease was apparently masking her comorbid depression. She was initiated with ECT treatments. She received 11 acute course treatments over 6 weeks and her MADRS improved from 47 to 9 with only mild memory dysfunction, namely with concentration and brief postictal confusion. After the 11th treatment, she began maintenance ECT. She reported feeling less tension and sadness. Her family reported increased interest, initiating outdoor activities with her husband, and overall a brighter affect. She also had improvement with Parkinson disease symptoms after the fifth treatment—both her tremors and handwriting improved. Her outpatient psychiatrist decided once she was in the maintenance phase to switch her from Remeron and Wellbutrin XL to Brintellix, which was titrated from 5 to 10 mg. At the last ECT treatment, the husband reported continued improvement, especially in motivation.

Severe depression is a common psychiatric illness in geriatric patients, with estimates in the range of 2 to 5 million patients with severe and subsyndromal depression, respectively. Depression in all forms late in life results in significant mental and physical complications, impaired neurocognitive function, decreased activities and instrumental activities of daily living, and increased morbidity. The World Health Organization reported that among all medical and psychiatric diseases, severe depression was the second leading cause of worldwide disability. Of significant health interest, patients with depression later in life have an increased risk of developing psychosis, suicidal ideation, suicidal intent, and suicidal completion. Thus, it is critical to provide a therapy that has a rapid onset of action in order to abate acute crises.

Older adult patients present with multiple psychiatric and medical illnesses. The frequency of reoccurrences and severity of depressive symptoms often increases with age. Severe depression in the older adult confers high levels of functional impairment and morbidity. Older adults are vulnerable to dehydration, weight loss, immobility, and complications from an array of comorbid medical conditions. ECT is indicated for older patients with severe psychiatric illnesses, including affective and psychotic disorders, catatonia of any etiopathology, and, in certain cases, neurologic disorders (Table 55.4f–1). Within the affective disorders spectrum, ECT can be used to treat both unipolar and bipolar depression, with and without psychotic features. For unipolar depression, ECT may be especially beneficial for older adult patients with psychotic or melancholic symptoms.

Geriatric patients with schizophrenia spectrum illnesses may also benefit from ECT, particularly if the psychotic disorder is new onset, acutely exacerbated, or treatment refractory. Schizophrenia affects approximately 1.1% of the U.S. population, and most geriatric patients with schizophrenia tend to manifest severe positive and negative symptoms that complicate their clinical prognosis and limit their adaptive functioning. Originally introduced for the treatment of schizophrenia, ECT is helpful in ameliorating both the positive and negative symptoms in patients who are nonresponsive to typical or atypical neuroleptic treatments.

Table 55.4f–1.
Indications for Electroconvulsive Therapy (ECT)

Major depressive disorder with melancholic features
Major depressive disorder with acute suicidality
Major depressive disorder with psychotic features
Treatment-resistant depression (TRD)
Bipolar disorder with acute mania
Bipolar disorder with depression
Bipolar disorder resistant to or intolerant of pharmacotherapy
Catatonia (of any etiology)
Schizophrenia resistant to or intolerant of pharmacotherapy
Parkinson disease resistant to or intolerant of pharmacotherapy
Major Neurocognitive Disorder due to Lewy Body disease resistant to or intolerant of pharmacotherapy
Major Neurocognitive Disorder due to Alzheimer disease resistant to or intolerant of pharmacotherapy
Epilepsy resistant to or intolerant of pharmacotherapy

Older adult patients often present with affective or psychotic disorders, which are secondary to a medical diagnosis. A thorough examination of the etiology of the psychiatric pathology should be undertaken to determine the association. In those instances where the underlying cause is related to the primary medical illness, medical care should be implemented. If no improvement is seen in the psychiatric illness, treatment should be initiated, beginning with less invasive options (i.e., pharmacotherapy, psychotherapy, social interventions) and incrementally building up to the administration of ECT. However, in cases where there is increased lethality (i.e., catatonia), ECT may be considered a first-line treatment. Delirium requires an exhaustive evaluation to identify and address underlying etiologies. However, ECT may improve the neuropsychiatric symptoms of this serious syndrome.

Neurologic disorders such as Parkinson disease and refractory epilepsy, which afflict older adult patients and result in severe affective or psychotic disorders, are also indications for employing ECT. Older adult patients with Parkinson disease may be at increased risk for severe depression, which may improve with ECT. These patients also often have side effects from drug–drug interactions; hence, ECT may be a favorable alternative to pharmacotherapy. Caution needs to be taken, though, when administering anesthetic agents during the ECT treatment course. Of note, some of the antiparkinsonian medications can result in depressive and psychotic symptoms. A collection of case studies reporting on a total of 22 patients with Parkinson disease found ECT to be beneficial for depressive and parkinsonian motoric symptoms, though considerable relapse in both motoric and affective symptoms occurred. Neuroleptic malignant syndrome, a life-threatening condition related to the use of neuroleptic medications, historically, in some cases, has been treated with ECT. However, ECT is not recommended as a first-line treatment, and prudent use requires careful monitoring of cardiac adverse effects due to pre-existing unstable blood pressure and muscular rigidity, which could be exacerbated during ECT sessions. Because ECT has anticonvulsant properties, as seen with subsequent increases in the seizure threshold after each treatment, ECT can be used to treat older adult patients with treatment-resistant epilepsy or those patients with status epilepticus. The risks and benefits must be weighed when applying ECT as other treatments may be more optimal such as vagus nerve stimulation (VNS), which is approved by the U.S. Food and Drug Administration (FDA) for treatment-resistant epilepsy.

Although not routinely performed, ECT can be administered to older adult patients with dementia. Patients with dementia, such as Lewy body or Alzheimer dementia, frequently develop severe affective symptoms, which can be treated with ECT if other therapeutic options fail. Several published case reports found ECT to be safe and tolerable, and efficacious, with a 40% response rate in older adult patients with dementia. Nonetheless, in patients who are diagnosed with dementia, the utmost attention must be paid to the progression of dementia and other neurocognitive effects in order to minimize cognitive impairments. As such, it is prudent to have a neuropsychological evaluation before commencing with ECT. While ECT is rarely utilized to treat combative or agitated behavior associated with dementia, even when other treatments are ineffective, there is limited research that has documented efficacy for those behavioral symptoms. The use of ECT as a therapeutic modality with patients who are diagnosed with dementia may be legally limited in certain states, and the treatment team would benefit from legal consultation regarding consenting procedures and the inclusion of the family in acute and longitudinal care plans.

Chest x-ray
Spinal series (if clinically indicated)

PRE-ECT EVALUATION

A comprehensive evaluation for older adult patients undergoing ECT should include a complete psychiatric history, neurocognitive evaluation, and medical/surgical history (Table 55.4f–2). The evaluation should examine potential proscriptive factors that could limit the effectiveness of ECT in geriatric patients.

A thorough and comprehensive psychiatric interview should be conducted that ascertains historical and current psychiatric diagnostic and treatment information. Given that older adult patients may have an extensive psychiatric history, it will be advantageous to obtain prior psychiatric records and to include a family member in the interview process to provide corroborating information.

Documentation of the psychiatric treatment history is of vital importance as it will have implications for the ECT treatment course. The historical use of ECT in patients has been found to be a predictor of future safety and efficacy. For instance, patients who benefited from ECT are more likely to benefit from future use of ECT, and those patients who showed no benefit may not benefit from ECT. Nonetheless, the prior ECT procedures

(BL vs. RUL, Stimulus dosing) need to be examined to ensure that ECT was properly conducted and followed American Psychiatric Association–recommended guidelines.

Psychotropic medications that were and were not beneficial need to be recorded in order to determine the level of treatment resistance and to plan the prospective acute, continuation, and maintenance treatment courses. Those psychotropic medications that were found to be beneficial may possibly be added to the acute ECT course to enhance the speed of response and therapeutic advantages and can be used in the continuation and maintenance phases to prolong remission. Collection of the antidepressant treatment history can be facilitated by standardized forms such as the Antidepressant Treatment History Form (ATHF). For example, the ATHF allows for the quantification of antidepressant medications in order to determine the adequacy of the treatment and the level of therapeutic resistance. Collaboration between the ECT practitioner and the geriatric psychiatrist at the initial psychiatric interview can lay the foundation for successful psychiatric treatment and provide an accurate understanding of the older adult patient's psychiatric needs.

A clinician privileged to administer ECT and an anesthesiologist should collect comprehensive medical and surgical histories. Ideally, this evaluation will occur as close as possible to the initial ECT session. Prior surgeries, ECT treatments, and exposure to anesthesia should be ascertained. Specifically, personal or family histories of malignant hyperthermia or other difficulties with anesthesia must be queried. Older adult patients may have multiple gastrointestinal, dental, cardiac, respiratory, musculoskeletal, or neurologic disorders that could complicate anesthesia or ECT procedures. Cardiovascular diseases are a major area of concern for increased morbidity and mortality in the treatment of older adult patients. These include recent myocardial infarctions (generally occurring within 6 months), congestive heart failure, coronary artery disease, aneurysms, and valvular disease. Brain tumors or conditions that increase intracranial pressure also present unique safety concerns. These conditions require careful clinical judgment and, in some cases (i.e., large, rapidly growing, or metastatic tumors), will present a clear contraindication to ECT. Recent hemorrhagic and ischemic strokes or conditions that predispose patients to cerebral vascular bleeding also pose significant safety risks. Poor dentition, loose teeth, and dentures should be evaluated as special precautions (i.e., customized bite block) may be required during the ECT treatment.

Older adult patients also require a careful physical examination with emphasis on the neurologic examination (including fundoscopic examinations to assess for papilledema) and dental, cardiac, respiratory, gastrointestinal, and musculoskeletal systems. Medical or specialty consultation for older adult patients can assist the ECT practitioner with the optimization or understanding of an illness rather than providing only “clearance” for ECT. The laboratory evaluation should be individualized and congruent with clinical indications. However, ECT centers should mandate minimum standards for this patient population, which should include a complete blood count (CBC), electrolytes, chest radiographs, and an electrocardiogram. Spinal radiographs should be considered in geriatric patients with a history of back or neck pain. Brain computed tomography (CT), magnetic resonance imaging (MRI), and electroencephalogram (EEG) are not routine or mandated but may be more beneficial and prudent in this population as compared to young adults.

The older adult patient’s current and prior pharmacotherapy should be reviewed due to interactions between different medications and ECT. Mood stabilizers, such as lithium, taken during the ECT treatment can increase the incidence of delirium after the ECT treatment and can impact seizure expression. The unique classes of antidepressant medications differentially impact ECT, with certain classes enhancing and others interfering with ECT. Monoamine oxidase inhibitors (MAOIs) can cause drug–drug interactions with anesthetic agents and should be discontinued before beginning ECT treatment. Tricyclic antidepressant medications (e.g., nortriptyline) are usually safe to use with ECT and may increase the therapeutic benefits. The use of selective serotonin reuptake inhibitors (SSRIs) in combination with ECT has received limited attention, but the use of selective serotonin-norepinephrine reuptake inhibitors (SNRIs), such as venlafaxine, has been shown to be beneficial when combined during the acute and maintenance ECT course.

Most antideprassants and antipsychotic medications have a synergistic effect with ECT; that is, the combined use of psychotropic medications and ECT can magnify the therapeutic effects. However, augmenting ECT with reserpine should be avoided as it could increase acute hypertension and the incidence of mortality. For patients with comorbid anxiety who use benzodiazepines, usage of those medications can reduce the seizure duration and should be tapered or discontinued before treatment initiation. Also, anticonvulsant medications should be tapered or discontinued 24 hours before each ECT treatment as they inhibit seizure induction and may result in increased stimulus dosage relative to the seizure threshold in order to elicit beneficial seizure activity. More research is warranted to decipher pharmacotherapy and ECT augmentation strategies, particularly with newer antidepressant and antipsychotic medications.

NEUROCOGNITIVE ASSESSMENT

A major concern regarding ECT by patients and their families is the perception that ECT causes cognitive impairment. Neurocognitive assessment of an older adult patient who receives ECT should be conducted before, during, and after the treatment course by a qualified clinician. The assessment before and after the treatment course should comprehensively assess neurocognitive functions, including premorbid intellectual ability, processing speed, attention, verbal and visuospatial memory, working memory, and executive function. Such a comprehensive evaluation allows for the establishment of a baseline to quantify the neurocognitive impact after the treatment course. Also, the baseline testing will aid in ruling out a diagnosis of primary dementia or delirium. Measuring neurocognitive functioning during the treatment course provides treatment-specific information to gauge the effects of ECT.

An exhaustive neurocognitive examination of patients considered for ECT may not be necessary unless there are indications of severe neurocognitive impairment. For example, research has found that certain cognitive domains, such as executive function, attention, and processing speed, are minimally impacted by ECT. The cognitive domain that has received the majority of attention is memory. An acute course of ECT has an immediate impact on anterograde learning and memory, but these effects tend to be transient and resolve within a week of the end of the acute phase. Thus, the practitioner designing and administering the neurocognitive battery needs to balance the information to be acquired with a patient burden. Especially for older adult patients, neurocognitive assessments can be taxing and counterproductive as the information can be compromised due to fatigue and decreased effort.

At a minimum, before and after the ECT course, the neurocognitive domains to be assessed include global cognitive functioning and retrograde memory (Table 55.4f–3).

In most clinical practices, global cognitive functioning is typically assessed using a standardized measure such as the Mini-Mental State Examination (MMSE) or the Montreal Cognitive Assessment (MoCA). A short measure such as the MMSE or MoCA gathers information to determine whether further tests need to be administered to clarify if any other neurocognitive deficits are present. Succinctly measuring global cognitive function taps into many cognitive domains in a short period of time (e.g., within 5 to 10 minutes) and is usually well tolerated by most older adult patients. Unfortunately, the MMSE, MoCA, and other common measures of global cognitive function are insensitive to the effects of ECT. Consequently, the baseline information will provide limited data to guide clinical treatment. In certain cases, it would be beneficial to use age and education-adjusted normative data, such as Mayo’s Older Americans Normative Studies, to account for the age-specific effects to fully appreciate the ECT-associated effects.

Table 55.4f–3.
Neurocognitive Assessment Before, During, and After Electroconvulsive Therapy (ECT)

Before and After ECT	**Global Cognitive Function**
	Attention
	Executive Function
	Learning and memory
	Confrontational naming
	Visuospatial construction
	Retrograde Memory
	Personal information
	Impersonal information
	Executive Function
	Cognitive flexibility
	Social Interaction
During ECT	**Time to Orientation**
	Eyes open
	Name
	Age
	Day of week
	Place
	Date of birth

The data generated from global cognitive function measures can be strengthened by also assessing retrograde memory. To accomplish this, standard scales can be employed that measure autobiographical information for personal and impersonal details. Personal information regards unique information, such as a prior birthday or employment history, whereas impersonal information regards information more of a “pop-culture” nature, such as a famous person, a famous television program, or a well-known event. If a standard scale is not used, the patient can be quizzed using information gathered from the clinical interview and corroborating information from a significant other. An investigation of 50 patients who were randomized to receive either right unilateral or bitemporal ECT found that patients showed a propensity to recall more personal information as opposed to impersonal information, regardless of the ECT stimulus dosage or efficacy outcome. However, relative to patients randomized to receive right unilateral ECT, those who received bitemporal ECT showed greater retrograde amnesia for personal and impersonal information. An important aspect of this study was the measurement and quantification of retrograde amnesia with a novel scale, which had the advantage of being directly translated into clinical practice. To increase the validity of the retrograde memory assessment, corroborating information should be gathered from a significant other.

During the treatment course, an important domain of cognitive function to assess is orientation, especially the time required to achieve full reorientation after each ECT session. Research has consistently shown that ECT has an impact on orientation and causes a period of disorientation immediately after each ECT session. A historical study compared bitemporal and right unilateral ECT and found that bitemporal ECT resulted in lengthier times to recover full orientation compared to right unilateral ECT. Although the study involved a small number of patients, it generated invaluable information and set a precedent for quantifying disorientation with an easy-to-use structured method. This method involves a clinician administering an orientation questionnaire. With a stop-watch or other method to measure time, timing starts as soon as the patient is able to breathe without assistance and ends when the patient accomplishes five out of six orientation criteria. These criteria include opening eyes and correct verbalization of name, place, day of the week, age, and date of birth. In one study, time to orientation was associated with the magnitude of retrograde amnesia (i.e., the lengthier time required to achieve orientation results in greater retrograde amnesia). Factors such as type of lead placement, stimulus dosing, and pulse waveform have been found to affect time to orientation, with bitemporal placement, higher dosages relative to seizure threshold, and sine wave resulting in longer times to achieve orientation. Ultimately, neurocognitive functioning is important to assess in order to quantify the adverse effects of ECT and to assist in clinical decision-making.

CONSENT

Informed consent is not a one-time event; rather, it is a continual process. As such, the initial consenting meeting is a vital component of the ECT treatment as it sets the stage for the consent process. Consenting to procedures before ECT is initiated is important, particularly for geriatric patients, given that there may be neurocognitive compromises related to the underlying illness. Many patients with psychiatric illnesses may lack the complete ability to provide informed consent, particularly those with a psychotic disorder, and this can conflict with the provision of treatment. Table 55.4f–4 provides suggested recommendations when obtaining informed consent.

Table 55.4f–4.
Suggested Informed Consent Procedures for Geriatric Patients Receiving Electroconvulsive Therapy (ECT)

Follow all local, state, and federal guidelines for the proper administration of ECT.
Qualify the patient’s capacity to provide informed consent.
Engage in an open conversation with the patient and a family member (if available) regarding the ECT treatment and the rationale for administration.
Utilize multimedia aids such as videos documenting an ECT treatment. Elicit feedback from the patient and answer any questions that arise.
The consent form must describe all aspects of the ECT course, including indications and contraindications in individual patients for ECT, ECT treatment procedures, anesthesia, adverse effects and respective benefits, alternatives to treatment, and rights to decline ECT treatment.
Use a standardized questionnaire to assess if the patient understands the consent form.
Have a witness cosign the informed consent form.
Document the consent process in the medical record.
Provide the patient with a copy of the signed consent form and place a copy in the chart.
Informed consent is a process, not a one-time activity, and must be monitored throughout the ECT course.

Prior to signing the consent form: Different states may have different requirements for informed consent. Prospective patients need a complete and thorough explanation of what ECT consists of, the procedures that will take place, the associated effects (both positive and negative), the length of the treatment, alternatives to treatment, and the continued care after the acute ECT course is completed. All of this should be written in the consent form that the patient will sign. Having an open forum of questions and answers makes this process informative and respects the patient's autonomy. This initial meeting can be further enhanced by watching a video of the ECT treatment with the patient and clarifying any related questions. The inclusion of the video ensures a comprehensive explanation of the ECT treatment and utilizes multimodal means of learning to help ensure that the patient is fully informed. Further, the initial consenting session can facilitate the establishment of trust between the patient and the doctor, clarify misconceptions, and help demystify ECT, as many older adult patients may view it as a negative treatment.

Building a supportive network for the patient is advantageous during and after the ECT treatment, and the consenting session is an ideal setting to lay that framework. The physician obtaining consent should invite a family member or caregiver to attend the informed consent meeting. This will allow for a thorough discussion of the ECT treatment process, allow the patient to feel that they are not alone, and provide the patient with someone to talk to after the discussion. Although it is not required, having a family member cosign the consent form provides further assurances that consenting procedures are being followed. For example, a retrospective chart review of 62 geriatric patients who received ECT in the New York state area found that 75% of those charts contained a family member's cosignatory, even in cases where the patient was documented to have the capacity to provide informed and voluntary consent. For older adult patients who are cared for at home, the family member is a vital component of the consent process and the overall treatment, as they will be primarily responsible for ensuring that the patient receives the appropriate aftercare. Also, the family member may have unanswered questions and negative stigmas associated with ECT that can be clarified in the consenting session. An additional step is to obtain the patient's consent for the clinician to contact a family member or the primary psychiatrist to obtain additional information on the patient over the course of ECT.

A common procedure to perform before treating a patient is to assess the patient's capacity to provide informed consent, especially for those patients who may have neurocognitive impairments. To provide informed consent, a patient must have the ability to provide voluntarily and fully informed consent. To assess the capacity to consent, the clinician (i.e., nurse, physician) should review the medical chart, acquire the patient's educational history and information, and administer a global cognitive examination such as the MMSE. These procedures will help guide the clinician in determining the level of capacity by which prospective plans can be arranged. For instance, should the patient have a limited understanding of their condition and treatment options, additional education regarding ECT, including a family member, and having the patient answer a questionnaire may help to increase the decision-making ability. An empirical study conducted at the Mayo Clinic comparing geriatric (mean age: 75.6, standard deviation [SD] = 5.87) and nongeriatric patients (mean age: 41.9, SD = 8.01) randomized to an additional half-hour session of education regarding ECT provided in a one-on-one format with a psychiatrist found that the provision of extra education increased the patient's knowledge base to inform their treatment decision. An elaborate battery of neuropsychological tests can be administered to comprehensively assess for any neurocognitive impairment; however, those procedures may not be necessary and could overburden the patient. Nonetheless, they are available to the physician and could be a source of additional information.

Some patients may be unable to voluntarily consent. This could be due to myriad factors, including psychiatric illness (i.e., catatonia), limited ability to make decisions, or blatant refusal. For those patients unable to voluntarily provide consent (different states may have different rules), the consenting physician should ask for an ECT consultation. The outside ECT consultation, usually performed by the chief of ECT services for the hospital, provides a second opinion of the patient's decisional ability and the immediacy for treatment. Particularly for those patients who refuse ECT, the secondary opinion provides further justification for the dire need for treatment based on the safety of the patient and others and can be used in legal proceedings to attain court-ordered treatment. As in voluntary consent, it is beneficial to include a family member in this process. The inclusion of the family member can help to mitigate any coercion or perception of coercion of the patient.

The consent process should be completely documented in the patient's medical record, including the number of meetings, who was in attendance, educational aids used, neuropsychological tests administered (if any), and the signed consent form. A copy of the signed consent form should be given to the patient. Since the consenting requirements and regulations can vary by state, it is critical to understand the respective laws for the consenting of the patient to receive ECT. For example, in the state of Texas, the patient is reconsented before each ECT treatment is provided. The reconsenting of the patient at each treatment further substantiates that consent is not a one-time decision; rather, it is a continual process, and the patient or family member could have new questions arise through each phase of the treatment.

ECT PROCEDURES

Anesthesia

All ECT treatments are provided while the patient is under general anesthesia, and for older adult patients, an anesthesiology consultation is of significant importance in order to determine the optimal anesthetic doses and minimize side effects. The anesthesia consultation should occur before the first treatment. Anesthetic doses should be re-evaluated before each treatment, with subsequent dosage adjustments based on the outcome of the prior treatments. Different classes of anesthetic medications are delivered, including neuromuscular blocking agents and hypnotic agents. The interactions between anesthesia and ECT can affect clinical outcomes, making it essential to have input and collaboration between the anesthesiologist and the ECT practitioner. For example, certain hypnotic agents can raise the seizure threshold, thereby inhibiting the production of seizure activity and resulting in a postponement of clinical efficacy. Hence, the provision of ECT in older adult patients is dependent upon multidisciplinary teamwork.

Age-related physiologic changes must be taken into account when providing anesthesia during ECT. Many older adult patients aged 65 years and older will have slow conduction in peripheral nerves, increased systolic blood pressure, reduced cardiac function, decreased hepatic metabolism, and decreased circulation time. These physiologic changes can result in potential delayed onset of anesthetic action as well as prolonged elimination. This can affect the ECT treatment in various ways. For example, as the seizure threshold is already high in older adult patients, proper dosage and timing of administering hypnotic agents must take into account the eliciting of a therapeutic seizure; otherwise, the ECT treatment may be ineffectual. Also, the administration of succinylcholine, a muscle relaxant, must be timed accordingly so that the body is relaxed upon ECT initiation in order to minimize muscle contraction and allow the patient to regain muscle control in parallel with regaining consciousness.

Different hypnotic agents have been used during ECT treatments, each with their respective physiologic properties that impact the ECT expression. A small study that compared the effects of different doses of methohexital, propofol, and etomidate in 10 patients with an average age of 54 years (range: 27 to 81 years) who received bilateral ECT found that propofol and methohexital at high doses significantly suppressed EEG seizure activity. Also, the use of etomidate, although it had minimal effects on seizure expression, resulted in the prolonged recovery of cognitive function. With the different anesthetic agents available and various administration techniques, expertise is paramount in synergistically pairing ECT and anesthesia.

With the use of anesthetic agents, there is the potential risk of increased confusion or disorientation after the ECT treatment. This side effect becomes critical when providing ECT to older adult patients as they are at an increased risk of ECT-associated adverse cognitive side effects in addition to normal age-related cognitive decline. One small study compared the cognitive adverse effects of anesthesia with etomidate or ketamine in 10 patients and found that short-term memory, as assessed by asking the patients to recall the names of four objects, was less affected by ketamine. The significance of this study is that it showed that different types of anesthetic medications could differentially affect cognitive function after the ECT treatment; however, the conclusions were limited by the small sample size, under dosage of the ECT treatment (i.e., provided right unilateral ECT at 200% above seizure threshold), and the fact that short-term memory was only measured with one nonstandardized cognitive test. On the contrary, in small documented cases, ketamine has been found to result in visual hallucinations and thus is rarely used in current clinical practices. A recent study of 79 patients in Britain found that low-dose ketamine with ECT did not provide any benefit in efficacy or verbal learning skills but increased the risk of adverse side effects. This study was powered only to detect large benefits.

Treatment Parameters

ECT treatment parameters can significantly affect its efficacy and tolerability. The three parameters that interact are pulse waveform, electrode placement, and stimulus dosage. Regarding pulse waveform, the first waveform introduced and has the greatest neurocognitive adverse effects is the sine waveform. Although this waveform is rarely used due to technologic enhancements in ECT devices and newer pulse waveforms (e.g., ultra-brief), a large-scale research study found that it is employed in some psychiatric practices and in some underdeveloped countries. However, the majority of academic and public institutions that provide ECT do so with brief or ultra-brief pulse waveforms. These two waveforms result in equivalent efficacy of sine wave but produce minimal neurocognitive side effects. Ultra-brief is the latest waveform developed and has been associated with faster rates of time to orientation after treatment, less neurocognitive adverse impact, and equivalent efficacy.

There has been, and there still remains, a debate as to what is the appropriate site placement for the ECT electrodes. There have been various electrode placement sites studied over the years of ECT research, and three sites have received considerable attention, those being bitemporal, right unilateral, and bifrontal (Fig. 55.4f–1). For all electrode placements, the patient's scalp will need to be prepared by applying a topical prep solution to clean the scalp, which will reduce impedance and allow maximum passage of the electrical stimulus.

For bitemporal electrode placement, each electrode is placed on each temple 1 inch above the midpoint of the line extending from the tragus of the ear to the external canthus of the eye. For right unilateral, one electrode is placed on the right temple 1 inch above the midpoint of a line extending from the tragus of the ear to the external canthus of the eye, and the other electrode is placed 1 inch to the right of the vertex. For bifrontal, each electrode is placed 2.5 inches above the outer external canthus of the eye. Bitemporal electrode placement was the first electrode placement used and has been shown to be significantly advantageous relative to the other two placement sites in terms of speed of response and remission. However, right unilateral placement, six times above the seizure threshold, has been shown to produce an equivalent response and remission rates despite requiring more time while also having minimal adverse neurocognitive effects. Bifrontal placement has received nominal attention but has shown high efficacy rates coupled with low adverse neurocognitive effects (Fig. 55.4f–2).

Stimulus dosing can be performed with one of two methods, either the age-based method or the empirical titration procedure. Both procedures have been found to produce successful inductions of therapeutic seizures.

In general, with the age-based method, stimulus dosage is adjusted by age, with younger age groups treated at low doses and older age groups treated with higher doses. Some clinicians prefer age-based titration methods because they may limit the number of subconvulsive stimuli. Regarding this method, either full-age or half-age dosing formulas can be applied. The full-age formula (dose = patient age multiplied by five) is more appropriate to use with right unilateral ECT as it typically equates to a dose close to six times the seizure threshold. On the other hand, the half-age formula (dose = patient age multiplied by 2.5) is more fitting with bilateral placement and results in doses approximately 2.5 times the seizure threshold. The age-based methods, though, do not account for individual variability, which could equate to the provision of markedly elevated stimulation with significant cognitive adverse effects.

The empirical titration procedure has been shown to sustain efficacy while limiting adverse effects through the containment of unnecessary energy. This procedure involves the delivery of an initial stimulus dose, which is nontherapeutic, followed by restimulation with increased intensity until a 20- to a 25-second interval of motoric or EEG manifestation of a seizure is observed. As found in clinical and research practice, the seizure threshold increases with age; thus, older adult patients require higher doses to achieve grand mal seizures. Even titration procedures are altered for older adult patients. Whereas with younger patients, those below the age of 50, the first stimulus may be administered at 5%; for the older adult, the starting stimulus is administered at 10%. Stimulus dosing is also influenced by choice of electrode placement. For subsequent treatments after the ECT titration session, bilateral and bifrontal electrode placement dosing is administered at moderately suprathreshold levels, defined as 1.5 times the seizure threshold. On the other hand, right unilateral ECT placement dosing is administered at moderately to markedly suprathreshold stimulation, which is 2.5 to 6 times the seizure threshold. These dosing strategies have been extensively researched and tested in order to ascertain their therapeutic effects.

Comparison of electric field strength and spatial distribution of electroconvulsive therapy and magnetic seizure therapy in a realistic human head model. *Eur Psychiatry*. 2016;36:55–64. doi:10.1016/j.eurpsy.2016.03.003.)

ECT Monitoring

During the administration of ECT, the induced seizure should be monitored via EEG and motoric response recordings. The EEG monitoring shows characteristic patterns of the grand mal seizure as well as the postictal suppression (Fig. 55.4f–3). The sites for recording the EEG are the frontal–mastoid and frontal–frontal montage, which will maximize the EEG seizure expression. During the tonic phase, hypersynchronous polyspike complexes are followed by polyspike and slow-wave complexes, and during the clonus phase, they are followed by sudden or gradual suppression. Most ECT-induced seizures last less than 90 seconds and consequently are deemed inadequate if they do not show bilateral generalization on EEG manifestations. For monitoring motoric expressions, the cuff technique can be used. This procedure involves applying a blood pressure cuff to a limb (i.e., arm or leg) before the administration of a muscle relaxant. Commonly, the cuff is applied just above the ankle of the left leg in order to observe ECT motor manifestations.

Continuous monitoring of hemodynamic functioning is maintained throughout the ECT treatment session. This is essential for anesthesia and the rapid shifts in parasympathetic and sympathetic outflow that occur after the electrical stimulus. As the patient receives the electrical stimulus, increased parasympathetic tone can produce asystole or significant bradycardia. These hemodynamic effects can be aggravated by subconvulsive stimuli or medications. The ECT-associated bradycardia can be mitigated by pretreatment with anticholinergics such as atropine or glycopyrrolate. During the seizure, heart rate and blood pressure generally elevate and may follow by a period of bradycardia. As a result, geriatric patients with any cardiac condition often require additional monitoring, management, and medications to dampen these effects.

Patients With Comorbid Medical Diagnoses

There are no absolute contraindications to ECT except cochlear implants. It is safe and effective in patients who have comorbid medical disorders with appropriate consultation of relevant medical specialists. Many older adult patients have pre-existing cardiovascular diseases such as hypertension, angina, arrhythmias, aneurysms, conduction abnormalities, and previous myocardial infractions. Consultation with a cardiologist prior to ECT for optimum management is warranted in these situations. Possible concerns involve the increased vagal (parasympathetic) tone during and shortly after each electrical stimulus, which can evoke brief bradycardia or asystole. The onset of the therapeutic seizure leads to elevations in heart rate and blood pressure. Postictal, there is a second period of heightened vagal tone, evidenced by bradycardia and ectopic beats in some patients. With careful management, cardiovascular risk can safely be mitigated in these situations. Anticholinergics such as glycopyrrolate and atropine given prior to ECT can subvert cardiac arrhythmias. Short-acting β-blockers such as esmolol and labetalol are often helpful in controlling hypertension and tachycardia during treatments. Other cardiac agents such as nifedipine, hydralazine, trimethaphan, and nitroglycerin can be used if indicated.

Intracranial mass lesions or increased intracranial pressure presents a serious risk factor for ECT. Optimally, subdural hematomas should be removed prior to treatment. Older adult patients with depression and who present with previous cerebral infarctions can benefit from ECT. However, the amount of time that should pass after a stroke to maximize safety is unknown. Otherwise, the incidence of cerebrovascular complications is minimal.

Osteoporosis, spinal disc disease, and spondylolysis may necessitate a higher level of muscle relaxation during ECT. Neurosurgical consultation for ideal management prior to treatment is advisable in these situations. Pulmonary status must also be maximized prior to treatment. Unique ventilation strategies may be employed for patients with lung disease.

ECT leads to transient increases in intraocular pressures. Patients with glaucoma should receive eye drops prior to treatment. Collaboration with ophthalmologists for patients with retinal detachments and acute close-angle glaucoma is essential. Patients with loose, uneven, or decayed teeth are at risk for dental injury with ECT. Dental consultation and unique block strategies may need to be employed in this setting.

ACUTE CLINICAL SAFETY AND EFFICACY

ECT is regarded as one of the safest and most effective somatic treatments for severe major neuropsychiatric disorders, particularly those for which alternate treatments have been ineffective. Its safety compares favorably to other procedures that require general anesthesia. The American Psychiatric Association Task Force on ECT, the National Network of Depression Centers Task Force on ECT, and the National Institute for Health and Clinical Excellence in the United Kingdom suggest that ECT is an efficacious acute treatment. In many systematic controlled trials, ECT has consistently been found to be superior to sham ECT (i.e., patients received only anesthesia) and pharmacotherapy.

The remission rates following an acute course of ECT have been found to vary between 20% and 80%, with an effect size as large as 0.9. This large range is dependent on an interaction of both ECT treatment parameters and patient clinical factors. For instance, in order for ECT to be effective, it must be appropriately applied with the respective therapeutic dosage, pulse waveform, and electrode placement. A controlled trial that compared fixed high-dose right unilateral and bitemporal ECT in older adult patients with major depression showed both electrode placements to be similar in terms of clinical outcome with comparable remission rates. However, bitemporal ECT was associated with higher cognitive deficits. In the Consortium for Research in ECT (CORE) study, which investigated the safety and efficacy of continuation ECT, approximately 80% of the total sample achieved remission during the acute phase with bitemporal, dose-titrated, brief pulse waveform ECT. Patients were treated three times a week, and standardized depressive rating inventories were collected within 24 to 48 hours after each treatment to systematically monitor mood change. Thus, a major conclusion of this study was that ECT could result in substantial acute efficacy when treatment is judiciously applied following a standardized therapeutic protocol with continual monitoring of patient symptom severity.

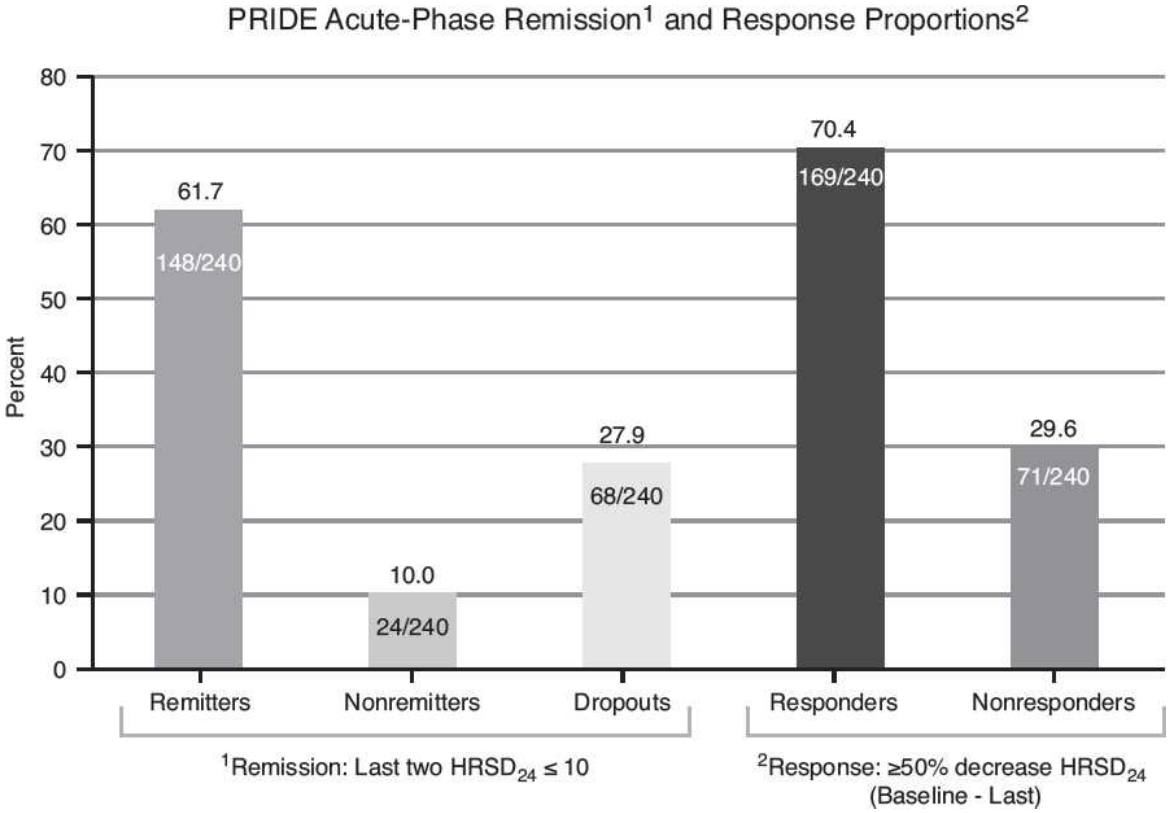

FIGURE 55.4f–4. PRIDE Acute-Phase Remission and Response Rates. (Adapted and reprinted with permission from Kellner CH, Husain MM, Knapp RG, et al. Right unilateral ultrabrief pulse ECT in geriatric depression: phase 1 of the PRIDE study. *Am J Psychiatry*. 2016;173:1101–1109.)

The PRIDE Acute Phase ECT for geriatric depression included 240 patients in the acute phase. In this study, the response rate was 70%, the remission rate was 62%, and the mean time to remission was 2.5 weeks (Fig. 55.4f–4). The PRIDE Maintenance Phase included 122 remitters from PRIDE Acute Phase and showed a decreased relapse rate in patients maintained on ECT + medication (13.1%) versus those maintained on medications alone (20.3%).

The significant benefit of ECT rests not only with its therapeutic benefits but also with the speed at which response and remission are achieved. Analyses from the CORE trial of 253 patients found that approximately 54% and 83% of the sample achieved a response (decrease in depression severity as measured by a standardized rating scale by a minimum of 50%) by the third and sixth ECT treatments, respectively. In terms of remission (level of depression severity found in the normal population), 65% of the sample met the criteria for remission by the tenth ECT treatment. Elucidating the speed with which ECT works, between the fourth and ninth ECT treatment, remission rates increased from 10% to 60%. As noted above, the rapidity of clinical benefit in ECT was supported in the PRIDE 1 trial of 240 patients, where the mean time to remission was approximately 8 to 9 ECT treatments (3 weeks). Given that pharmacotherapy may take many weeks to achieve a steady state and produce results, and psychotherapy likewise may take time for results to show, ECT is the most important therapeutic choice for those patients who are in critical condition due to acute and severe psychiatric illness and in need for quick response.

Early retrospective studies that utilized chart reviews found conflicting results, with some indicating ECT to be ineffective for older adult populations and others finding it to be both safe and efficacious. With technologic improvements and advances in ECT practice, recent controlled clinical trials have found ECT to be highly effective in older adult patients. Comparisons with tricyclic antidepressants, MAOIs, and even SSRIs found ECT to be superior. In fact, age has been found to be an influencing factor for the therapeutic effects of ECT. A report from the CORE trial showed that age was positively associated with treatment response and subsequent remission. In that report, 90% of the older adult cohort, relative to 64% of the younger cohort, responded with ECT. Further examination of the data discovered that the greater response was only valid for those patients with psychotic features and suggested that the presence of psychosis and older age interacted and resulted in higher response rates. That is, older adult patients without psychotic features and younger patients showed comparable response rates, but older adult patients with psychotic features showed higher rates of response relative to younger patients. The PRIDE 1 study also came to a similar conclusion with data that patients 70 and older had an odds ratio of remitting 1.89 greater than those aged 60 to 69.

ECT is a highly effective treatment for the majority of older adult patients, even those who are 75 years and older. A prospective study of 268 patients examined three categories of older adult patients: those younger than 60 years of age, those between 60 and 74 years, and those aged 75 or older. Although the younger cohort had relatively lower seizure thresholds, no differences were found between groups concerning the number of treatments or electrode placement. The middle cohort was found to have higher response rates compared to the younger cohort, but no efficacy differences were found between the middle and older groups.

This study found that ECT is beneficial for the oldest old and confirmed earlier clinical reports that older age is positively associated with higher seizure threshold levels.

The effectiveness of ECT is paralleled by its timeliness in the onset of response, which may result in shorter and less costly hospital stays. A small controlled trial of 13 patients over the age of 65 found a 21% reduction in depression severity (as rated on a standardized scale) after the first ECT treatment and a 36% reduction after the second. The depressive symptom impacted most after the first treatment, with a decrease of 36%, was “reported sadness.” On average, four treatments resulted in a decrease in depression severity by 50%, though the investigators cautioned that response varied per individual case and that further research was required to assess the time to respond and remission in older adult patients. To a degree, these data are synonymous with the findings of the CORE and PRIDE trials, which found ECT to have a quick onset of action.

ECT can be judiciously applied to a spectrum of geriatric patients with comorbid illnesses, including cerebrovascular disease or dementia; however, there is a dearth of information from systematic randomized controlled trials. Retrospectively, chart reviews and clinical reports support ECT to be efficacious in the treatment of severe mood disorders in older adult patients with concomitant dementia, neurocognitive impairments, or stroke. The presence of cerebrovascular abnormalities did not minimize the therapeutic response; nonetheless, when applying ECT to geriatric patients in the presence of concomitant cerebral pathologies and dementias, prudent observation and monitoring of symptomatology and adverse neurocognitive effects become paramount.

The optimal benefit from ECT in older adult patients is dependent upon eliciting therapeutic seizures. Both clinical and research practice has shown that older adult patients have higher seizure thresholds and thus require higher doses of electrical stimulation. One controlled trial reported that in 20 patients, 2 required stimulus doses that exceeded the levels available on commercial ECT devices in the United States. The FDA has limited the ECT devices to 576 millicoulombs; as such, a small percentage of older adult patients with remarkably high seizure thresholds may not benefit due to the inability to elicit seizure activity.

CONTINUATION AND MAINTENANCE ECT SAFETY AND EFFICACY

A cogent constraint of ECT is the high relapse rate after completion of the acute treatment course, with proneness for relapse being greater during the first week and the month after remission. Consequently, though older adult patients may show better response and remission with ECT relative to younger patients, they may also have higher rates of relapse. One study that followed 51 older adult patients for 1 year during and after treatment with either ECT or pharmacotherapy treatment for major depression found that 41% of the total sample was rehospitalized at least once within the first year, and 46% (6 of 13) of the ECT group was rehospitalized during the first month after acute treatment.

Many factors may contribute to the high relapse found following a successful acute course of ECT, including residual depressive symptoms, concomitant physical illness, and psychosocial factors. Residual depressive symptoms are those symptoms that did not abate with antidepressant treatment that could substantially increase the risk of reverting back to baseline status or could be a precursor to the development of a new depressive episode. Many older adult patients who suffer from comorbid physical illness may be burdened with additional stressors that complicate continued recovery from the acute phase. Poor physical health, specifically cardiovascular disease and diabetes, has been linked to both affective and anxiety disorders. Thus, older adult patients with comorbid physical medical illnesses may be more at risk for re-experiencing a return of psychiatric pathology after a period of remission. Finally, older adult patients with increased psychosocial stressors such as lack of autonomy, living alone, or decreased activities and instrumental activities of daily living may be more susceptible to relapse occurrence. Nonetheless, the goal of continuation and maintenance therapy is to sustain the period of remission while simultaneously limiting the associated adverse effects.

The CORE trial was designed to determine whether continuation pharmacotherapy (lithium plus nortriptyline) or ECT (bilateral electrode placement 150% above the seizure threshold) resulted in a better outcome, and the results indicated that both were equivalent in prolonging remission. Of the patients randomized to the continuation ECT condition, 37.1% relapsed, and 46.1% retained remission. For those in the continuation pharmacotherapy group, 31.6% relapsed, and 46.3% retained remission. The time to relapse was similar in both groups, with patients in the ECT arm relapsing after an average of 9 weeks and those in the pharmacotherapy arm after an average of 6 weeks. Although both of these therapeutic modalities were deemed better than no treatment after attaining remission in the acute ECT phase, they were moderately effective in retaining the antidepressant benefits produced during the acute ECT phase.

A probable benefit of maintenance therapy with ECT is the lack of drug–drug interaction. Older adult patients usually receive multiple medications for the management of physical health-related issues. The resulting polypharmacy from mixing a multitude of medications, such as antidepressants, mood stabilizers, analgesics, and cardiac medications, could result in iatrogenic effects. Moreover, older adult patients may be sensitive to the pharmacologic properties of medications, and proper administration must be monitored to ensure the attainment of the full therapeutic effects while limiting harmful reactions. In such cases where older adult patients are extremely sensitive to the effects of medications or they have a coexisting medical condition that limits the use of psychiatric medications, ECT can be a viable alternative. However, given the cardiovascular adverse effects of ECT in older adult patients, especially those with pre-existing hypertension or unstable cardiac activity, continued ECT use needs to be combined with careful and comprehensive monitoring of cardiovascular functioning. For instance, one study of patients over the age of 75 found the development of transient hypertension and sinus tachycardia during and after the administration of ECT. Although the transient phenomena were considered “normal,” they still merit monitoring and evaluation.

ECT ADVERSE EFFECTS

ECT is one of the safest and most well-tolerated somatic treatments, with a documented mortality rate of 0.002%. The majority of side effects are limited to the time during and immediately after an ECT treatment, with the majority of side effects persisting for a short period of time after a complete acute course and others lasting for a longer period of time (i.e., 6 months and longer) (Table 55.4f–5). Three broad side-effect categories for ECT are systemic, neurophysiologic, and neurocognitive.

Systemic Effects

Mortality associated with ECT is most commonly attributed to cardiovascular or respiratory complications. Death can result from myocardial infractions or ruptured arrhythmias, ruptured aneurysms, and brain herniation. Pulmonary aspiration is rare but particularly important to prevent in patients with chronic lung disease. Short-lived increases in blood pressure, pulse, cerebral blood flow, and intracranial pressure present risks for older adult patients but, in the majority of cases, are well tolerated. Ideally, the modern practice of using muscle relaxants prevents fractures that often occurred in the early days of ECT practice. Patients can still suffer from dental complications (i.e., fractured teeth, temporomandibular joint pain) or complain of myalgia, but these risks are extremely rare with the advent of anesthesia and placement of bite blocks. Muscle pain can be related to the use of depolarizing agents such as succinylcholine, and headaches can be successfully treated with over-the-counter analgesics and often improve with time. Pretreatment for musculoskeletal pain can also be beneficial in certain cases. Some older adult patients complain of nausea and vomiting following ECT sessions. Antiemetics such as ondansetron, metoclopramide, and prochlorperazine can be administered to treat these symptoms or prophylactically prior to ECT.

Table 55.4f–5.
Side Effects Related to Electroconvulsive Therapy (ECT)

Headache
Hypertension
Cardiac arrhythmias (bradycardia, tachycardia, asystole)
Nausea
Tongue bite
Temporomandibular joint pain
Disorientation
Delirium
Anterograde amnesia
Retrograde amnesia
Prolonged seizure
Precipitation of mania
Drug–drug interactions
Anesthetic complications
Aspiration
Breathing complications
Myalgia
Dental complications
Postseizure myocardial infarction
Postseizure stroke
Tardive seizure
Scalp burn (very rare)
Bone fractures (very rare)
Spinal disc prolapse (very rare)
Compression fracture (very rare)

Neurophysiologic Effects

Research involving humans and animals indicates that neither ECT nor brief seizures impart structural brain damage. This is further substantiated by carefully controlled imaging studies. However, seizures lasting more than 180 seconds should be aborted with an anticonvulsant anesthetic agent or a benzodiazepine. Lengthy seizures and status epilepticus could theoretically lead to neuronal injury if the patient becomes hypoxic. This is unlikely, though, as ECT patients are well oxygenated, and most prolonged seizures are easily suppressed. Spontaneous seizures after treatment (tardive seizure) are rare but, in their event, require careful evaluation and management. Postictal delirium can involve disorientation, agitation, and confusion and is best managed with supportive interventions, minimization of environmental stimuli, and judicious use of medications such as benzodiazepines.

Neurocognitive Effects

Concerns about the neurocognitive effects of ECT are likely the most limiting factor for the provision of this therapeutically beneficial treatment. Numerous studies have systematically examined the neurocognitive sequelae associated with ECT, taking into account various ECT parameters and neurocognitive domains, as well as the effects of the underlying psychiatric disease. Although research and clinical findings have varied per patient sample and method of ECT administration, the overarching conclusion is that ECT does result in transient negative cognitive effects, particularly in the memory domain.

The ECT parameters studied have included sites of electrode placement, stimulus intensity, and pulse waveform. There are three prominent electrode placement sites used clinically: bitemporal, right unilateral, and bifrontal. Anecdotally, bitemporal is thought to produce the fastest speed of response but also carries the burden of having the most neurocognitive adverse impact. Right unilateral, on the other hand, is thought to have similar properties in terms of efficacy yet a more benign neurocognitive profile. Bifrontal, too has been suggested to have high efficacy with benign neurocognitive effects. Numerous clinical trials studying the impact of bitemporal and right unilateral ECT have consistently found right unilateral to be more cognitively sparing relative to bitemporal, notably with regard to memory functions.

Examinations of bifrontal ECT have been limited due to small sample sizes and inconsistent procedures in terms of dosing strategies. However, the CORE group, in its large-scale, controlled trial of three electrode placements, compared the cognitive effects of bitemporal, right unilateral, and bifrontal placements administered with brief pulse waveform during an acute ECT course. The study found that all three electrode placements were equivalent both in efficacy and neurocognitive adverse effects. However, that study was limited by missing data and patients who exited the study early. A study conducted in Belgium compared bifrontal and right unilateral electrode placements administered with ultra-brief pulse width during the acute course. That study found that both bifrontal and right unilateral were equivalent in both efficacy and neurocognitive outcome.

Studying electrode placement must take into account the interactions of stimulus dosing and pulse waveform. Research has found a consistent direct correlation between stimulus dosage and neurocognitive impairment. With the introduction of stimulus dose titration in the 1980s, the dosage of ECT is limited to the amount needed to provide a therapeutic seizure. This has helped to minimize the negative neurocognitive side effects that were found in earlier use of ECT when higher doses were applied. An empirical example of the effects of stimulus dosage was found in a controlled, double-masked clinical trial that compared bitemporal and right unilateral ECT. The treatment conditions were bitemporal ECT at 150% above the seizure threshold and right unilateral ECT at 50%, 150%, or 500% above the seizure threshold. Efficacy and neurocognitive assessments were performed before the treatment, after the sixth and last treatments, and 1 week after the last treatment. The investigators found that the neurocognitive effects of right unilateral ECT were dependent on the stimulus dosage utilized to provide treatment. When administered at higher doses, statistically and clinically significant differences were found between the right unilateral groups, with the higher dose (i.e., 500% above seizure threshold) resulting in greater time to reorientation and more anterograde memory impairment (i.e., memory for new information). However, even at the highest right unilateral dose, bitemporal electrode placement resulted in more cognitive impairment in the domain of retrograde amnesia.

Another controlled investigation examined the acute neurocognitive effects of only right unilateral ECT delivered at either a fixed high dose (403 millicoulombs) or a moderate titrated dose (2.25 times the initial seizure threshold). The findings mimicked those of other studies and showed that right unilateral ECT at a fixed high dose produced greater neurocognitive effects than the moderate titrated dose in the domains of time to orientation, global cognitive function, and retrograde memory. Thus, when deciphering the neurocognitive effects, electrode placement and stimulus dose must both be examined in order to sufficiently understand the interaction. With the recent advent in studying the interaction effects of pulse waveform, there has been inconsistent information. For example, a randomized, controlled clinical trial found that ultra-brief, relative to brief pulse, was associated with fewer neurocognitive effects, regardless of electrode placement. However, in another randomized controlled clinical trial that compared brief and ultra-brief pulse waveforms in patients treated only with right-unilateral electrode placement, empirical dose-titrated ECT found that both pulse waveforms produced similar clinical and neurocognitive outcomes. That is, the study suggested that ultra-brief pulse waveform has no neurocognitive advantages relative to brief pulse waveform. Further research is warranted to clarify both the clinical and neurocognitive effects of the ultra-brief pulse waveform.

Time to reorientation (i.e., the time needed after the end of each ECT session to regain orientation) is greatly impacted immediately after each treatment, with resolution following in time after treatment. Like other cognitive domains, orientation time is affected by electrode placement, stimulus dosage, and pulse waveform with bitemporal electrode placement, higher stimulus dosages, and sine waveform resulting in lengthier times to reorientation. In a study that compared bitemporal and right unilateral ECT, both electrode placements showed relatively similar patterns of orientation recovery over the course of treatment, indicating that subsequent ECT treatments do not incrementally prolong orientation recovery time. For instance, in that study, the first and last two treatments were compared, and no within-group differences were found regarding reorientation time, even though between-group differences were observed. Of interest, with right unilateral ECT, age was positively related to recovery time, with older patients regaining orientation at a faster rate than younger patients. The positive association between age and reorientation time was mitigated by the lengthy reorientation time in the bilateral group. Research of the pulse waveforms has consistently found that sine waveform results in the longest time to regain orientation, followed by brief pulse, and finally, ultra-brief pulse.

When assessing neurocognitive effects, acute and long-term effects must be examined. Acutely, ECT results in modest impairment of many domains, including visuospatial and verbal learning and memory and global cognitive function. However, those effects typically resolve quickly within 1 week to 1 month after the end of the acute ECT course. A study of 45 depressed patients who received ECT (administered with right unilateral or bitemporal electrode placement) compared those above and below the age of 60 on a battery of neurocognitive tests at set time points. The study found that immediately after and at long-term follow-up, patients showed improvement in neurocognitive measures of attention, verbal fluency, and memory for visual shapes. The investigators concluded that the improvement in neurocognitive function may have been related to decreased depression severity or the ECT-associated activation of dopaminergic and serotonergic neurotransmitters.

Consequently, in terms of short- and long-term neurocognitive effects, the domain of neurocognitive function is greatly impacted is retrograde memory. Initially, retrograde memory was thought to resolve over time after the end of the acute phase, with a substantial recovery of personal memories. Earlier research found that retrograde amnesia could be predicted by the global level of cognitive functioning before the initiation of ECT.

A community study of ECT practices in the New York area showed evidence that retrograde amnesia is a persistent effect of ECT and that some autobiographical information may be lost. Seven New York hospitals (three community hospitals, two private hospitals, and two university hospitals) were included in the study, and a total of 347 patients who were longitudinally followed for 6 months provided outcome data. Focusing on the neurocognitive outcome, the seven treatment facilities differed due to ECT practice differences at the respective sites. For instance, one center administered ECT with a sine waveform that was associated with more effects on psychomotor speed and memory for autobiographical information. The significance of the site differences indicated that there is no one uniform practice of ECT administration and that outdated methods of ECT treatments that result in greater neurocognitive effects are still used in community practice.

More importantly, the study found that retrograde memory deficits persisted for at least 6 months and were related to ECT technique, female gender, lower premorbid intelligence, and advancing age. Of equal importance, the number of ECT treatments with bitemporal electrode placement was associated with the amount of retrograde amnesia, even at the 6-month time point. However, that study was critiqued as it used an autobiographical memory interview that has not been shown to have validated psychometric properties. Further research is needed with psychometrically sound measures of autobiographical information to confirm or refute those findings. Nonetheless, older adult patients may be more prone to ECT-associated adverse cognitive effects, and treatment with right unilateral electrode placement, empirical dose titration, and ultra-brief pulse waveform may help to mitigate the cognitive effects.

Autobiographical memory, the area mainly affected by ECT, can be categorized into two types: One that focuses on personal memories and one that focuses on impersonal memories (i.e., public events). A clinical trial of patients treated with either right unilateral or bitemporal ECT, who were compared to a healthy control group, found that memory for impersonal events was more affected than memory for self, and greater deficits were found in those patients treated with bitemporal ECT. The pattern of memory loss showed that more recent events, those closest in time to the delivery of ECT, were the most vulnerable to the ECT effects. Also, those events that were patient determined to have low salience were most vulnerable to the effects of ECT.

The most reliable data on the neurocognitive effects of acute ECT come from the PRIDE Phase 1 study. In this study, cognition was assessed at baseline and within 72 hours after the last ECT session. Some domains showed no significant change from baseline. These include verbal learning, delayed free recall of words, and initiation/perseveration. Other domains showed statistically significant declines, which were assessed to NOT be clinically meaningful. The assessment of modest impact was based on small effect sizes and the cognitive domains remaining intact/average to mildly impaired. The affected domains include autobiographical memory consistency, short-term free recall and recognition of learned words, phonemic fluency, processing speed, visual scanning, and cognitive flexibility. The assessment of autobiographical memory consistency should be considered in light of research showing that this domain typically declines over a period of time equivalent to an index ECT course, meaning that the decrease observed in this study does not necessarily imply neurocognitive impairment.

A neurocognitive domain that is often overlooked in both clinical and research arenas is the patient's view of their cognitive experience, which is commonly referred to as subjective cognitive functioning. Many older adult patients with affective disorders will complain of memory difficulties, short attention spans, and slow psychomotor speed. Although the neurocognitive functions may be intact based on formal neurocognitive testing, the patient's subjective experience needs to be considered, especially with regard to ECT. Due to the negative stigma associated with ECT, which some older adult patients refer to as the “shock,” their subjective viewpoint is a factor in the efficacy of the treatment. Prior research found that patient self-rating of neurocognitive function was related to a depression severity self-rating scale, with higher scores on the depression scale correlating to greater subjective cognitive impairment scores. During and following an acute ECT course, patients showed significant improvement in subjective cognitive function, indicating that their memory had improved regardless of electrode placement type (bitemporal or right unilateral). The change in self-evaluation of neurocognitive functions was correlated with improvement in mood and was also related to the degree of retrograde amnesia.

Finally, it is important to note that ECT produces marked and significant improvement in health-related quality of life measures, with the largest gains in the mental health component of this measure.

In summary, the PRIDE Studies were an important addition to the clinical literature on ECT. Acute Phase focused on the efficacy and tolerability of Right Unilateral Brief Pulse ECT (RUL-BP). Maintenance Phase focused on neurocognitive side effects and how to prolong remission.

Pride Acute Phase was a multisite randomized trial of 240 adults who were 60 years old or older and in a depressive episode of major depressive disorder. Patients were given an acute course of Right Unilateral Ultra-Brief Pulse ECT combined with flexible-dose venlafaxine targeted to 225 mg qd. ECT was given 3 times per week, and the average number of sessions to produce remission was 7.3 ECT treatments. Results of Acute Phase, 62% of patients met remission criteria, 10% did not remit, and 28% dropped out. The vast majority of nonremitters met response criteria with a total response rate to ECT of 70%. Remission was quite rapid, with a mean time to remission of approximately 2.5 weeks. The largest contributor to remission was ECT, as the cohorts with the highest and lowest venlafaxine dose had no differences in efficacy outcomes. PRIDE Acute Phase 1 showed that ECT is an effective treatment for moderately severe and severe depression in geriatric patients. Insomnia was also studied in PRIDE Maintenance Phase with the finding that ECT + venlafaxine had no modest benefit for insomnia which was linked to the general improvement in depression symptoms. A comprehensive neurocognitive battery was given 72 hours after the last

ECT to assess for neurocognitive side effects. One hundred and seventy-two patients completed the study.

The PRIDE Phase 2 trial was designed to determine if pharmacotherapy alone was equivalent to pharmacotherapy + ECT. In Maintenance Phase, remitters (n = 120) were randomized to either pharmacotherapy (venlafaxine + lithium) or pharmacotherapy plus RUL-UBP (Ultra brief pulse) ECT. ECT was administered in a symptom-titrated algorithm-based longitudinal ECT protocol referred to as STABLE. STABLE mandated 4 additional ECTs in the first month after completion, as well as symptom-titrated ECT as needed. Results of the study indicated that pharmacotherapy + ECT was more effective than pharmacotherapy alone.

OTHER NEUROSTIMULATION THERAPIES

Although ECT is a highly effective treatment for major affective disorders and other severe treatment-resistant psychiatric conditions, its use is limited due to associated adverse cognitive effects and high relapse rates after the acute phase. In order to remedy the negative effects of ECT and to increase the delivery of efficacious treatments, other neurostimulation modalities are being developed as antidepressant therapies as well as therapies for other mental health and brain conditions. Many of these neurostimulation modalities have mechanisms of action that differ from ECT and, thus, could provide an understanding of the underlying pathophysiology of neuropsychiatric disorders. These modalities include transcranial direct current stimulation (tDCS), transcranial alternating current stimulation (tACS), Vagus nerve stimulation (VNS), rapid transcranial magnetic stimulation (rTMS), magnetic seizure therapy (MST), and deep brain stimulation (DBS). Most of these newer neurostimulation therapies are in an experimental phase of development, especially in geriatric patients.

Transcranial Direct Current Stimulation and Transcranial Alternating Current Stimulation

Transcranial direct current stimulation (tDCS) applies a weak direct current (1 to 2 mA) with scalp electrodes. Depending on how it is delivered, anodal stimulation increases cortical excitability, while cathodal stimulation increases cortical inhibition. tDCS has variable effects on long-term potentiation (LTP) or long-term depression (LTD). As a result, this tool has been applied to a wide array of studies investigating neuroplasticity and cognitive neuroscience. Generally, tDCS is well tolerated and has the potential to alter cortical activity beyond the stimulation session. Therapeutic research has focused on depression, stroke rehabilitation, cognitive remediation, and, more recently, studies of dementia. Contemporary work suggests that clinical outcomes with tDCS may be enhanced by coupling it with cognitive remediation, antidepressants, or other concurrent treatments. In late life, most tDCS studies have focused on enhancing cognition among patients with dementia or at risk for dementia, such as those with mild cognitive impairment. In a large ongoing study (Prevention of Alzheimer dementia with Cognitive remediation plus tDCS in Mild cognitive impairment and Depression (PACt-MD), older patients with remitted depression, mild cognitive impairment, or both are randomized to receive tDCS to the frontal cortex combined with cognitive training versus sham tDCS plus sham cognitive training. The main objective is to assess whether enhancing prefrontal cognitive function with tDCS and cognitive training could prevent cognitive decline in these high-risk populations.

Transcranial alternating current stimulation (tACS) is another form of transcranial electrical stimulation that delivers an alternating instead of a direct current to targeted regions. Also focusing on cognition in older adults, tACS delivered to the frontal and temporal regions of the brain seem to be a promising strategy to enhance cognition, especially when the frequency of the alternating current is matched to naturally occurring brain oscillations, for example, theta oscillations.

Rapid Transcranial Magnetic Stimulation

Rapid (or repetitive) rTMS is a noninvasive neurostimulation technique that applies alternating magnetic currents, which then produce an electrical current in the underlying cortical areas. rTMS has been under significant investigation as a treatment for major affective disorders and other neuropsychiatric illnesses.

The use of rTMS is attractive to many clinicians as it has been shown to be safe and well-tolerated. In 2008, the FDA-approved rTMS for treating adult patients with unipolar major depressive disorder for whom one antidepressant treatment has failed to work. The main side effects reported include temporary headaches and scalp pain at the site of stimulation. As rTMS has been investigated for more than 20 years, safety guidelines have been generated by expert scientists to guide clinical decision-making regarding rTMS treatment parameters. A limitation of using rTMS in a geriatric sample is the presence of cortical atrophy in the prefrontal cortex (the usual site of stimulation). Cortical atrophy is inversely related to treatment outcome with rTMS and has been found to be a predictor of nonresponse. Deep TMS (dTMS) claims to have deeper cortical penetration and may address this issue. However, to date, there are no neuroimaging corelated studies in this regard.

While fewer and smaller studies have been conducted to evaluate rTMS in older adults with depression, the current literature suggests that it is as effective in this population as in mid-life and that it is well tolerated.

To date, two studies examined the effects of rTMS in older adults with depression in randomized controlled trials.

The first study examined the results from two previous clinical trials by selecting older adults. It showed that only bilateral high-frequency rTMS, and not unilateral or sham rTMS, was effective in achieving remission in older adults with depression.

The second study examined the efficacy, tolerability, and cognitive effects of high-dose deep rTMS in older adults with depression. In this study, older adults with depression were randomized to sham or active deep rTMS delivered over the dorsolateral and ventrolateral prefrontal cortex 5 days per week over 4 weeks. The study found that the remission rate was higher with active than sham rTMS (40.0% vs. 14.8%). However, there was no change in cognition and no serious adverse events.

Recently a novel form of rTMS called theta-burst stimulation (iTBS) that clusters TMS pulses into high-frequency bursts of TMS pulses at 50-Hz repeated every 200 milliseconds for 2 seconds on and then 8 seconds off for a total of 600 pulses has been shown to be as effective as rTMS for adults with depression. The advantage of iTBS over traditional rTMS is that each treatment is about 3 minutes instead of 30 minutes, and multiple-session-per-day protocols are now being investigated to accelerate treatment. However, to date, no studies on geriatric depression are available.

Magnetic Seizure Therapy

Magnetic seizure therapy (MST) is a neurostimulation therapy currently being studied that utilizes rTMS at high frequencies (i.e., 50 to 100 Hz) to induce therapeutic seizures. The goal of MST is to focally induce therapeutic seizures, containing the cortical spread of the seizure, in order to maximize efficacy while limiting adverse effects. Initial research in primate and human models found MST to be safe and well tolerated, with evidence of limited negative effects. Several pilot follow-up studies in humans further suggested that MST is effective for the treatment of acute depression and comparable to ECT but with fewer cognitive side effects. For example, in one trial, 20 patients with unipolar or bipolar major depressive disorder were randomized to receive focal MST, with the magnetic stimulating coil placed over the frontal cortex, or nonfocal MST, with the coil placed over the vertex. The results found the treatment to be modestly efficacious, with response and remission rates of 50% and 15%, respectively. Of benefit, MST showed limited cognitive effects in the domain of retrograde amnesia for autobiographical memories. Also, there were no adverse effects in the domains of global cognitive functioning, verbal and visual anterograde learning and memory, or time to orientation. Patients also reported subjective improvement in cognitive functioning.

In another study, 37 patients with depression completed at least nine ECT or MST (100-Hz) treatments in a randomized, double-blind protocol. While response rates were low for both arms, MST did not differ from ECT in effectiveness. However, MST was associated with improvements in psychomotor speed, verbal memory, and cognitive inhibition and with no cognitive decline.

A large study is currently underway that includes patients over 65 to compare MST to ECT to confirm whether they are equivalent and to compare their cognitive effects: the Confirmatory Efficacy and Safety Trial of Magnetic Seizure Therapy for Depression (CREST-MST) study. This study is a randomized, double-blind, noninferiority clinical trial comparing MST for treatment-resistant depression to RUL-UB-ECT. Treatment is administered 2 to 3 days per week until reaching remission or up to 21 treatment sessions. Remission from suicidal ideation is also being measured. MST also holds promise to have antisuicidal effects in treatment-resistant depression. Given the higher risk of suicide among older adults suffering from depression, its use in this population may also be further justified by this specific effect.

Vagus Nerve Stimulation

Vagus nerve stimulation (VNS) was approved by the FDA in 2005 as an adjunctive antidepressant treatment for patients with treatment-resistant depression. VNS involves implanting a device similar to a pacemaker that produces brief, intermittent electrical stimulation to the vagus nerve. This neurostimulation modality was investigated in two large-scale, randomized, controlled clinical trials. The first, an open-label trial, found VNS to be safe and tolerable, producing limited side effects grouped into two categories, surgery related and stimulation related. These side effects were transient and resolved over time; even those related to stimulation lessened over time, and many patients reported substantial adaptation to side effects such as increased cough and hoarseness during active stimulation.

In terms of efficacy, the second trial, double-masked and sham-controlled, found no difference between active and sham VNS during the acute phase. However, during the long-term open-label phase in which all patients received active treatment, depression severity decreased as measured by both clinician and patient reports, and modest response (29.8%) and remission (17.1%) rates were found. Although VNS has shown some benefits, it remains unclear how to adequately provide dosing. In the initial study, the majority of the patients received high-dose VNS, whereas, in the second study, VNS doses were lower.

Of significance, there were no negative cognitive side effects found, and conversely, patients showed minimal improvement in the cognitive domains of psychomotor speed and executive functions. However, this improvement was supposed to be related to the improvement in depression as opposed to directly related to VNS. Nonetheless, VNS could be an option for geriatric patients with treatment-resistant depression who have not benefited from other available antidepressant therapies and who, for any medical reasons, are unable to undergo ECT.

VNS has also been studied in pilot investigations for cognitive enhancement in Alzheimer dementia, and a large study is ongoing to evaluate it as a potential treatment for MCI using a noninvasive transcutaneous VNS (tVNS). tVNS stimulates the afferent auricular branch of the vagus nerve, located medial of the tragus at the entry of the acoustic meatus. Given that it does not require surgery, it is likely to be safer for older adults.

Deep Brain Stimulation

Deep brain stimulation (DBS) involves the surgical implantation of a pacemaker-like device that sends continuous electrical stimulation to a specifically targeted region in the brain. DBS has been safely used with beneficial results in patients with severe movement disorders such as Parkinson disease. The procedure is considered invasive but safe, as the surgery takes place while the patient is awake, and the electrode leads are placed directly in cortical tissue.

There has been recent interest in using DBS to treat severe affective disorders based on initial anecdotal observations that patients with movement disorders appeared brighter during the course of treatment. DBS has been granted FDA approval and Humanitarian Device Exemption for the treatment of obsessive-compulsive disorder (OCD). DBS is currently being studied for a variety of other psychiatric and neurologic conditions, including addiction, anorexia nervosa, depression, and schizophrenia. While these studies are not specific to geriatric populations, one geriatric condition for which DBS is actively being investigated with some promising early results is Alzheimer dementia. Lazanos reported a case with improved cognition with DBS that has prompted interest in studying DBS for dementia.

Preliminary studies in Alzheimer dementia suggest that DBS of the fornix increases glucose metabolism in the temporal and parietal lobes and that these changes tend to be associated with clinical benefits among patients older than 65. Larger and confirmatory studies are underway. Other preliminary studies investigated DBS of the Nucleus Basalis of Meynert, with findings suggesting a cognitive and metabolism-stabilizing effect. Similar preliminary evidence of a clinical stabilizing effect is suggested by DBS to the ventral capsule/ventral striatum.

FUTURE DIRECTIONS

Algorithmic treatment development is a crucial future step to optimize the application of ECT and neuromodulatory interventions in the older adult. This work will aid clinicians in sequential treatments or complex regimens with multimodal approaches. Further work to identify risk factors for neurocognitive side effects and minimize this burden for patients will improve outcomes. Another important area is optimal continuation and maintenance treatment which is still a major problem and poorly understood.

With the advent of newer somatic noninvasive therapies such as tDCS, rTMS, and MST, and surgically invasive therapies such as VNS and DBS, additional research is warranted to understand their effects in geriatric populations. Research thus far has found these neurostimulation therapies to be cognitively benign and possibly cognitively enhancing with promising clinical efficacy in relatively younger cohorts, and this will have to be tested in the geriatric population and can have significant therapeutic implications when treating older adult patients, especially those with pre-existing cognitive deficits. MST, in particular, though presently in developmental stages, could be a new frontier in convulsive therapies through its proposed mechanism of action that facilitates therapeutic seizure induction coupled with little neurocognitive effects.

With newer neurostimulation and convulsive therapies added to the psychiatric therapeutic armamentarium, future directions will need to begin to address the issue of developing high-caliber treatment algorithms tailored to the individual geriatric patient. This could involve utilizing different neurostimulation modalities in different treatment courses. For example, patients who benefited from acute ECT may receive continuation TMS to prolong the period of remission. Also, the combination of neurostimulation modalities with pharmacotherapy requires an understanding of how to refine that administration in order to enhance clinical efficacy, particularly in older adult patients who are prescribed multiple medications. The goal of these treatment algorithms should focus on defining the optimum delivery of somatic therapies that maximize therapeutic benefits and minimize unnecessary medications and adverse reactions. In addition, these evidence-based algorithms for geriatric patients should underscore the importance of neurocognitive assessments and effects when determining clinical management with somatic and multimodal therapies. These scientific advances in geriatric psychiatry will contribute to the continued evolution of novel and advanced somatic therapies for older adult patients.

55.4g Psychosocial Factors in Psychotherapy of the Older Adults

JOEL I. SADAVOY, M.D., F.R.C.P.(C)

The term *psychosocial,* as used here, refers to social and environmental elements in an individual’s life that interact with and affect the individual’s mental health and intrapsychic processes. Such elements may be conceptualized at two levels: an intermediate level of factors arising within the immediate environs of the patient (e.g., friendship or family relations) which may change and evolve over time and a macro level of factors associated with more stable societal, ethnic, and cultural norms. A clinician’s knowledge of history can be an important element in establishing a therapeutic alliance with a patient in psychotherapy. The impact of historical events remains a vibrant but unseen influence on the internal world of the older adult patient who often feels that this aspect of their life experience and identity is not valued or understood. While history is not modifiable it is an important aspect of a psychotherapist’s tool kit. It informs therapy by providing context for therapeutic understanding and decision making. For example, for the oldest old, key earlier life decisions such as whether to marry or have children may have been heavily influenced by the experience of the trauma of victimization or combat during wars, local conflicts, terrorism, worldwide economic depression, or political oppression. In turn, such factors can strongly affect the degree to which an individual will age successfully, since marital status and family support are strong predictors of health and well-being in late life. The aging demographic continues to evolve as older adults live longer. The number of centenarians in the United States grew from 53,000 in 2010 to over 90,000 in 2020, with similar increases in numbers of individuals living to extreme old age in other industrialized countries. We are still in the early stages of understanding the psychosocial implications of living to extreme old age. Perhaps of special relevance in this group are the psychological impacts of isolation and loneliness in the context of recurrent loss as individuals outlive most of those around them who once provided love, identity, and companionship.

RELATIONSHIPS

The passage of time leads to major changes in a patient's social network. In youth, time is often viewed as an ally, an opportunity for growth, and a time when new interpersonal roles and novel social partners are preferred. In old age, time is no longer an ally, eroding many life achievements and increasing the preference for emotionally close social relationships. Perhaps most profound are the changes associated with the loss of relationships through death or other factors.

While old age does not inevitably lead to isolation and loneliness, these are important targets of psychotherapeutic and social intervention in late life. Social disconnection is associated with suicide ideation, attempts, and deaths in later life and has been identified as a modifiable intervention target to reduce suicide risk. Loneliness is a related, but slightly different concept which may be defined as a state of emotional distress from lacking desired interpersonal relationships. In numerous studies loneliness and isolation have been correlated with depression, dementia, substance and chronic physical health conditions common in older adults such as hypertension, heart disease, diabetes, and conditions sensitive to chronic inflammatory stress response. Understanding loneliness and isolation as key determinants of physical illness, and psychopathology in older adults can guide psychotherapy. Targeted Interventions include behavioral activation which has been shown to increase social interactions and decrease loneliness among homebound older adults and engage psychotherapy for depression in later life.

There is a convincing body of research in support of the concept that better social relations is related to better health and longer life in older adults. Loneliness and the absence of better social relations are risk factors for psychiatric disorders, particularly depression, and stress-related physical illnesses and disability. A recent U.S. study of over 3,000 adults found that social disconnectedness predicted higher levels of perceived isolation, which in turn predicted higher depression and anxiety symptoms. Conversely, higher levels of depression and anxiety symptoms predicted perceived isolation and social disconnectedness.

What is less clear in the literature on social relations is which elements are most critical, for example, social support, social network, social integration, or social participation. The majority of data support the concept that older adults who are part of what have been termed more socially endowed, diverse, or resourceful networks have better mental health. Such networks are characterized by a greater number and variety of social ties, with whom the individual is intensely involved. It is also unclear whether all relationships confer health benefits. It may be that social relationships with friends and confidantes (so-called discretionary or nonkin relationships) have a greater effect on mental health than relationships with kin, particularly children. There remains some debate as to whether it is the nature of the network itself or whether it is the individual's perception of and satisfaction with support that is the most important protective factor. Both seem to be important factors and should be taken into account when evaluating individual patients.

It seems fairly clear that beyond the nature of the network, the presence of negative interactions is a source of stress while perceived positive relations buffer stress. Hence, it is perhaps not surprising that strong social support helps to buffer depression, and married adults are at a lower risk of depression than unmarried or widowed adults. There is an ongoing debate over the elimination of the bereavement exclusion criterion from a diagnosis of depression in the Diagnostic and Statistical Manual 5. A recent study, for example, has found a high rate of significant depressive symptoms in bereaved older adults who lost their spouse (although major depressive disorder was not associated with bereavement). It is estimated that one in six men and almost half of women over the age of 65 are widowed, and of these about a third will experience complicated bereavement, increasing their risk of depression and associated morbidity and mortality. Moreover, even uncomplicated bereavement can be associated with depressive symptoms which, while they may not reach threshold criteria for a diagnosis of major depression, nevertheless also may impair function and increases their risk of medical comorbidity and mortality. However, psychosocial resources including religious and spiritual belief, and practice, social and family support and Erikson’s concept of vital involvement expressed in commitment to life tasks are moderating or protective factors which might be modifiable and enhanced by therapy.

Bereavement, while almost always difficult, may also be a release from an oppressive relationship, liberating the remaining spouse to resume old pursuits or take on new roles and responsibilities. For example, one spouse spoke eagerly about her ability to return to the academic research and teaching she had relinquished due to the demands of providing care to her ailing spouse.

During care of older adults, as with younger adult patients, it is important to make no assumptions about the significance of loss but rather to explore the specific meaning of loss to each patient. It is important, too, to be aware that the bereaved spouse may need time and energy to develop new roles and relationships and they may struggle with how to identify themselves beyond being a spouse and partner. Other social changes may emerge that are supportive following bereavements. For example, widowed older women receive more help from friends than married women while widowed older men are the most likely to receive support adjusting to practical and emotional changes following the loss of their spouse.

Beyond bereavement, marital relationships in old age also are changed by physical or cognitive impairment, and shifting patterns of dominance and responsibility. For example, the basic nurturing role previously carried out by a loving wife may now fall into the unaccustomed hands of her husband in the face of her decline with Alzheimer disease. He experiences not only loss, but also the need to offer comfort and care, behaviors and feelings with which he has always been awkward. Guilt, resentment, and some anger sometimes emerge as a consequence. Conversely, the physical or mental decline of one spouse may elicit kindness and nurturing late in life that was absent in earlier years. For example, a haughty, narcissistic wife became “chastened” by her awareness of her own decline. While she agonized over her own losses, she also realized that the husband she previously demeaned and devalued was now her greatest ally. He welcomed the new role and the respect he began to feel from her, revealing a nurturing, loving side she had never seen before.

Sociocultural trends in relationships will impact the aging process. For example, in North America, there has been a trend, especially among well-educated, high socioeconomic groups, to delay child-bearing in favor of focusing on career and financial advancement, only to find that fertility has been significantly reduced. This, in turn, often leads to inadvertent and unwanted childlessness and deep late-life regrets. In addition, greater participation of women in the workforce may preclude them from taking on the more traditional role of caregiver and further contribute to the relative lack of children able to support aging parents. Cultural patterns of marriage have also changed. Japan’s almost universal marriage tradition stood in contrast to patterns in Europe, where marrying at a later age or not marrying has been much more common. Interestingly, however, Japanese women are increasingly delaying marriage and childbirth, with a high percentage of the unmarried expressing the intention to never marry. This inevitably leads to a dramatically lower birthrate. The result will be a growing cohort of childless older adults in many societies. Childlessness would seem to disadvantage individuals as they age, but research suggests that childless individuals compensate for not having the support of children by strengthening relationships with friends and collateral kin such as siblings, nieces, and nephews. Nevertheless, in times of increased need for support in old age, childless older adults are left without adequate levels of care. Women are more likely to be childless than men, and childless older adults of both sexes are much more likely to live alone or in institutions and have fewer face-to-face contacts than their peers who have children. However, interestingly there appears to be little difference in psychological well-being between childless seniors and those who are parents.

A social safety net can mitigate social pressures associated with old age. For example, in the United States social insurance provides the financial resources to allow many single older adults to live alone. Similarly, housing alternatives for seniors including congregate living, supportive housing, and community-based social welfare services reduce isolation and dependency on others. However, it is not only practical support that is crucial to the mental well-being of older adults. Rather, for many, it is the presence of true confidants that is key to warding off demoralization and depression. In this regard, informal care networks may be equally or more relevant.

Research on the impact of interventions to enhance social inclusion and reduce isolation is of limited quality. Still the evidence that exists suggests that interventions such as music and singing, intergenerational programs, art and culture, and multiactivity interventions may be associated with positive health outcomes. Such data may support psychotherapeutic interventions that address depressive withdrawal, age-related demoralization, and poor social engagement.

Despite enhanced social support, older adults, especially women, without supportive families often face an emotionally impoverished old age. This is particularly true if governments erroneously assume that families will care for older adults. Childless older adults or those emotionally or geographically distant from their children will obviously be disproportionately disadvantaged by such policies and more likely to be alone. Clearly, these issues have a central effect on the focus of psychotherapy. Problem-solving or interpersonal psychotherapy approaches for isolated older adults will construct and address a different array of problems and issues than for older adults who have strong support structures, such as the management of issues of abandonment or deficits in intimacy.

The nature of intimacy similarly shifts, often in the direction of distance and isolation. The equal partnership between married spouses may shift to a caregiver—care recipient relationship with consequent loss of mutuality and intimacy. Sexuality is a particular victim of the switch from spouse to caregiver. Friendships, easily maintained during younger, more active years, often become much more difficult to sustain, especially in the face of physical impairments. Driving is more of a challenge, evening and night travel more fearsome, and gathering places less welcoming and accommodating. Healthy and active older adults are more able to maintain equitable friendships where both friends can contribute equally. More frail older adults receive more than they give, becoming so-called “overbenefited” in their friendships. Equitable friendships or relationships in which older adults (women) give more than they receive lead to higher morale than in overbenefited women. Interestingly, older men seem to establish more equitable relationships than women.

Affiliation and intimacy seem to be more important to women than to men, although such data should be approached with caution as there have been few studies on the needs of men for intimacy in old age. Some work has shown that, when compared to married men and married and widowed women, widowed men less often have relatives living close by and are less likely to be members of community organizations but may be no more likely to describe themselves as lonely. The data on the importance of intimacy has not been well verified for all cultural groups. For example, there's some evidence that Black women place more importance on functional aid (as opposed to intimate affiliation) than White women. Studies of Japanese older adults have demonstrated an association between social support and self-rated health and mortality, results that were also noted in studies in Sweden and Finland.

Friendships are more than just emotionally supportive. Data suggest that the existence of a close friend and to a lesser extent kinship contacts increase the likelihood of maintaining functional independence.

The pattern and meaning of change in friendship networks in old age are different for men and women. For example, married men may derive much of their self-esteem from their career and family and value friendships significantly less than married women. In old age, men may establish increased casual friendships but there is little indication of increased close relationships and overall data suggest that men (in contrast to women) decline in many measures of friendship. After retirement, men may establish casual friendships but turn to their spouses for personal meaning and self-worth previously derived from their work. With the death of a spouse, married men may be particularly vulnerable to isolation because of their relative lack of friendships and other community connections developed earlier in life. In addition, their spouse may have been their primary or only confidante and may also have been their link to the community. Married women may be relatively protected in bereavement because they are more likely to have other confidantes, both relatives and friends, and belong to community organizations. As a result, they have the opportunity to find other meaningful roles and relationships that may mitigate the loss of their spouse. However, for both men and women, social support from family or friends can only go so far. It is more difficult to lessen the internal loneliness that stems from the loss of the person who is often the spouse’s most significant attachment figure and companion. Indeed, other relationships may not be able to alleviate that loneliness and the loss of the life partner must be mourned and therapy may provide an important venue for working through. While loneliness is a natural human experience it may not be easy to reliably measure using standard instruments. Why is this? While lack of social contact and support are key antecedents that can lead to loneliness, it is not equivalent to social isolation. Social isolation is an objective state and more easily identified and quantified while loneliness is an internal dysphoric and unpleasant experience which is related to the experience of deficiencies in social relationships; for example the feeling, right or wrong, that while there may be many people around to talk to, nobody truly understands. This is a common expression of loneliness among older adults such as those who are caring for a spouse with dementia. There are a number of loneliness measures both direct (self-report of loneliness) and indirect (measuring factors associated with loneliness without using the word itself to avoid the problem of stigma of self-identification) which yield different results. For example, a direct question revealed greater prevalence of loneliness among older women while an indirect questionnaire showed greater incidence among older adult men.

Illness and other age-related events like bereavement take their toll on friendship networks. These networks become depleted although the number of contacts may be less important than their quality. The maintenance of fewer emotionally meaningful relationships may provide sufficient social connectedness and protection against loneliness. Nonetheless, even for naturally outgoing personalities, the avenues for establishing and maintaining new friendships are often blocked. One outcome is the erosion of relationships in which the old person’s history, accomplishments, desires, and ambitions are known by their friends. Increasingly, aging fragments and isolates. Data on adaptation in the oldest old are not consistent. The oldest old, in contrast to the young-old, often become overburdened by illness and frailty, and even previously adaptive personality types with strong positive self-assessments often cannot successfully adjust to their disabilities. Some data indicate that subjective well-being can be sustained through positive self-referential attitudes. Results of these changes include physical distance from longstanding friendships and often, although not invariably, reduced frequency of contacts, which increase feelings of aloneness and create reliance on more casual opportunistic relationships such as with neighbors. While certainly not universal, this process of change contributes to creating a special context imposed by old age on the therapeutic process. Old patients, often through no fault of their own and despite their efforts, may present with a burden of aloneness. This is especially true for those who are unmarried or bereaved. This can create in therapists the anxious sense that they must be more than a treater, responding to an unspoken request for friendship and becoming for the patient the only place and person to offer a safe, intimate emotional haven. The therapist may find these challenges to be somewhat daunting as they may stir up the therapist's own fears about illness, incapacity, and death. The therapist may feel overwhelmed and worry about being engulfed by the patient's helplessness and dependency. In response, the therapist may distance themself from or reject the patient, labeling them as chronically ill, beyond help, and incapable of change. The reverse reaction may also occur in the therapist who wishes to halt or turn back the aging process. In this situation, the therapist may see therapy as life sustaining or even lifesaving. As a result, they may avoid termination rather than face the inevitability of the patient's and, perhaps, their own death.

Blanket rules about friendship and its impact in old age are inadvisable since the nature of friendships differs for each person depending on their psychological makeup. People differ in their need for, as well as their capacity to have, friends; their ability to maintain them; the nature and intensity of their friendships; their ability to do without them; and their standards for with whom they allow intimate confiding relationships. For example, Donald Winnicott suggests that those who never fully invested in friendships earlier in life may be better able to "make do" in old age with more superficial acquaintances without experiencing aloneness. Such individuals may be more invested in activities and personal expressions of creativity that are not dependent on contact with others (i.e., a well-developed capacity for self-soothing and self-sustenance). The implication for psychotherapy is that therapists are most effective when they explore in depth with patients the nature of their friendship networks, their satisfaction with the level of intimacy and support, and strategies either for mourning lost relationships that cannot be replaced or for ways of enhancing their friendship networks to fulfill their needs. Many patients do not volunteer such information in therapy or may not be aware of their needs; hence, it must be elicited and explored actively. No specific psychotherapeutic techniques have been developed for dealing with these issues, but by extrapolation from other work (e.g., on depression), interpersonal psychotherapy, cognitive-behavioral approaches, problem-solving therapy, or perhaps reminiscence therapy may be effective tools.

Assessing social isolation includes evaluating ease of relating to others; feeling of isolation from others; extent of sharing feelings with a significant other; connecting with others when needed; feelings of engagement with others; and feelings of aloneness and friendlessness.

Beyond friendship, sexual and other physical intimacy may diminish or disappear from the life of the old person—no one to touch or be touched by. The literature suggests that sexuality among older adults can remain vibrant and pleasurable although the determinants of sexual activity are varied and may change over time. For example, in one large study positive determinants of sexual activity included a positive attitude toward sexuality, sexual debut before age 20, having a very happy relationship and a physically and mentally healthy partner, good global health and mental health, being married/cohabiting, and drinking alcohol more than three times a week. Sexual frequency and interest is also enhanced when there is a change of partner in old age. Sexuality in older men is less researched than women and often focused on the impact of erectile dysfunction and there is limited cross-cultural, gender identity, and sexual preferences research. In the psychotherapeutic context, sexuality is often rich therapeutic territory but discussion of sex in old age may challenge the openness of the patient and the skill and beliefs of the therapist. Data continues to support a conclusion that seniors are embarrassed or otherwise avoidant of talking about sexual problems with health care professionals who may be viewed as uncomfortable, not knowledgeable, or disinterested.

Positive attitudes to sexuality appear to be maintained in old age. While true as an isolated piece of data, findings also must be seen in the full psychosocial context, in which older adults over a certain age are often widowed and without partners and with limited opportunity to form new close bonds. The lack of a suitable partner is the key predictor of sexual activity among women. One study found that 82% of residents of subsidized independent-living facilities had not had intimate sexual contact in the past year, although many had at least one experience of hugging or other touching. Hence, for example, intimate touching may become the domain of the medical encounter during physical examination or the nonsexual hugging of children, grandchildren, or friends. Physical isolation becomes especially evident in retirement or nursing homes or other institutions where predominantly old women live in an unusually gender-homogenous environment. Whatever sexual or intimate interest remains is put in cold storage, often forever. It is also true that sexual activity and pleasure vary dramatically, often directly associated with the availability of sexual opportunities in relationships. Psychotherapists and other caregivers need to be sharply aware of the patient's needs and reactions under these circumstances, elicit the impact on the patient, and incorporate the realities into the treatment, either working toward change or acceptance. The therapist must also be aware of countertransference reactions in this area. Unresolved conflicts over parental sexuality may lead the therapist to avoid any discussion of sexuality or to regard the older client as asexual. As in all psychotherapies, the therapist must monitor their reactions to the patient through active self-examination. By bringing these reactions into awareness, the therapist can minimize their potential to have detrimental effects on the therapy and, instead, use them to better understand the patient.

The psychosocial phenomenon of loss of intimate relationships in old age may have special impact on the form of the psychotherapeutic relationship. Therapists are often and easily experienced by the isolated patient as a wished-for substitute for the lost relationship. Therapists may feel alone with the patient in their depleted world as well as uncomfortable pressures to adopt the roles or behaviors of friend, confidant, protector, advisor, or advocate. The therapist who identifies too closely with the patient's problems may be immobilized by pity or sadness that impairs their ability to empathize with or promote change in the patient. On the other hand, the therapist may shrink away from the patient's sadness, thereby increasing rather than easing the client's isolation and grief.

While old age is a time of substantial change and requires great adaptability, satisfactions may still abound. However, they tend to be encountered within a narrower frame, focused more on family relationships and very close friendships. For many, the loss or unavailability of friendships/relationships promotes a kind of centripetal emotional force that draws some older adult persons into their families and somewhat away from other relationships particularly when faced with the challenges of failing health. The loss of confiding relationships may be especially clinically relevant, since some research suggests that these relationships are protective against depressive disorder. Effective psychotherapy and environmental interventions that support the patient's need for new relationships can counter some of the effects of loss of confidants. While attention to relationships during therapy is important regardless of the patient's age, it is especially necessary with older adults. Assessment and intervention must elicit not only the presence of instrumentally supportive relationships, but also which of them are sustaining of self-esteem and maintenance of identity.

The increasing importance of family relationships with advancing age adds an element to the psychotherapy of older adults not found as prominently among younger adult patients. Therapists often must take into account age-induced dependency issues in families and the conflicts these issues engender, such as forced intimacy and caregiving situations with adult children. For example, conflicts arise over the different perceptions of need that the older adult parent has. Children may be overly anxious and protective, aging parents inappropriately resistive of needed help or exaggerating of their helplessness. While family assistance and caring are crucial supports for the aging person, the therapist must be wary of assuming that family can substitute for friends. Indeed, friendship interaction is positively correlated with self-esteem, while kinship interaction is not. Whatever the pattern, the psychotherapist of older adults must take the family system into account, sometimes involving the other family members directly in the therapy or helping the older adult person develop appropriate interpersonal patterns of interaction. Flexibility of psychotherapeutic technique and interventions is essential. The usual adult–therapist stance broadens when treating older adults as psychosocial issues associated with frailty, dependency, and relational shifts impinge, often rendering individual assessment and focal intervention inadequate. Impelled by these realities, the therapist often must combine overt roles of advocate, intermediary, and educator with the more traditional psychotherapeutic roles and interventions. Sometimes, this means reaching out actively to families, social agencies, or medical caregivers, roles that are often unaccustomed for psychotherapists. While therapists need to be flexibly supportive, they also need to examine their motivations when intervening on their patients' behalf. Transference- and countertransference-induced forces can lead therapists to inappropriately cross therapeutic boundaries, unwittingly adopting the idealized roles of adult–child or spouse seemingly in response to real psychosocial needs, but actually impelled by dimly understood or unconscious dynamic forces in the therapeutic relationship. Therapists dealing with relationship changes in aged patients also must be prepared to deal with their own feelings of loss, grief, fear, and loneliness and wishes to idealize, dominate, or avoid painful psychological issues that may be generated during treatment of the psychosocial stresses of old age.

ROLE CHANGES

Occupational role changes impose relatively unique challenges on older adults. This group is almost universally forced to give up important sources of self-esteem, creative activity, social networks, and the organizing effects of job expectations. The importance of work is exemplified by the finding that nonemployed older women have lower self-esteem. Reactions to retirement differ. Retirement may be eagerly anticipated and handled well, especially among those who used to be called blue-collar workers and those with the resources, resilience, and creativity to use newfound leisure time in a satisfying way. Others, such as some professionals, often avoid retirement, and may find the loss of their occupational roles difficult. Either way, the psychotherapist must be keenly aware of the centrality that work-related roles play in structuring life and the changes to this structure imposed by aging. These factors are especially relevant in the so-called young-old, 65 to 75 years, who are more likely to have freshly encountered the issues of occupational role change. For example, an emotionally distant marital relationship may have been quite stable and acceptable when work substituted for unavailable marital closeness. After retirement the emptiness of this form of relationship becomes much more evident and can lead to depressive reevaluation of life and choices. While difficult, this is also a time of therapeutic opportunity. Since retreat into work-related defenses is no longer possible, patients are forced to confront themselves and reexamine their long-held beliefs about others, especially their spouses.

Here, examining with patients the sources of their feelings both longstanding, deriving from early, perhaps unconscious developmental factors, and more immediate, for example, associated with distorted modes of perception and thoughts about a partner who seems to want to care but is constantly rebuffed, is important. In the more advanced years, these issues generally recede, either adapted to and worked through or overwhelmed by other more pressing issues. However, when fresh, the psychosocial pressures of occupational role change, especially when combined with other events, such as spousal bereavement, often emerge as states of vulnerability, fearfulness, and impaired capacity to seek new, alternative sources of gratification.

Beyond its function as a source of personal gratification and self-esteem, the workplace serves an important social function. For example, one of the important considerations in retiring for women is the finding that they tend to give up work-related relationships after retirement. Working may have disrupted other familial and social roles and may not have allowed time for employed women to nurture or even maintain other relationships. In retirement, women may feel disconnected and that they have no role or purpose in life, particularly as other relationships may no longer be active. Hence, retirement creates a more impoverished social life for women, increasing their vulnerability to emotional reactions that accompany lost relationships.

As implied already, parenting roles may change dramatically in old age. For example, well-established patterns of parental dominance and reliance by children on a strong authoritative parent often suddenly reverse as parents become more frail and dependent. Conflict, guilt, or fear may invade a previously stable system. Particularly vulnerable are family systems whose members adapted to earlier conflicts by establishing distance, for example, children moving away from the pressures created by demanding, unreasonable, critical parents. In such circumstances, the increasing needs of aging parents may impose pressures on children to care for parents for whom they have had longstanding conflicted feelings. The psychotherapist must be careful to examine and understand the parent–child system and beware of taking stereotyped approaches to aging parents since the patterns of parental role changes are quite varied. For example, frailty and fear of being alone and incapacitated often lead older adult patients to complain about the inattentiveness of adult children. Taken at face value, the psychosocial needs of the patient often are indisputable. However, the pattern of the family members' reactions to the patients' needs is rooted in the long history of their relationships with each other.

One daughter found herself trapped providing care to her aging parents and subjected to a pattern of mistreatment well established earlier in her life. She found visits to her parent's home very difficult, but if she didn't go, her mother would repeatedly attempt to contact her and berate her when a visit eventually occurred. The daughter chose to go regularly to forestall intrusions and having to cope with her mother's disapproval and agitation. Her sense of obligation towards her parents kept her involved in a situation where she felt that there was little or nothing she could do to bring about positive change for herself or her parents. Another child spoke about her sadness at what she saw as the "changing of the guard," meaning she was now caring for the people who previously cared for her. To be effective, the therapist must be sensitive to the emotional forces that are preventing the family from adapting to the new, age-induced needs of the parent.

Many older adults, mostly women, become caregivers to a spouse who develops dementia. They are subject to an array of stressors that lead to what has been termed caregiver burden. Burden is associated with disproportionate rates of both psychiatric and physical morbidity. Psychosocial factors as well as personal characteristics impact the resilience of caregivers and their capacity to manage this new and generally unwelcome new role. Dementia caregiving is particularly arduous. It differs from other forms of caregiving in that caregivers of persons with dementia have more unmet needs and strain than nondementia caregivers with higher levels of physical, psychological, social, and economic consequences. They spend significantly more hours per week providing care, report greater impact on employment, greater strain, mental and physical health problems, less time for leisure and other family members, and family conflict. Behavioral and psychological symptoms of dementia (BPSD) are well-recognized sources of stress and burden on family and other informal caregivers of persons with dementia. The emotional effects of caregiving include facing helplessness in the face of this disease while concurrently dealing with chronic grief and mourning. This form of chronic grief is often unrecognized or diminished even by well-meaning others and hence has been called disenfranchised grief. Such grief can become "complicated" and the longer it goes on the more likely it is to induce depression.

Family caregivers concurrently balancing employment with caregiving roles for older adults are a vulnerable subset of caregivers. In the United States, as of 2013, about 60% of family caregivers of people with dementia were employed. A recent survey examined 1,839 Canadian employees who were also caregivers. It revealed that those who were dealing with high or medium levels of caregiving demand for family members with dementia had significantly greater role demands and challenges on measures of perceived stress, depressed mood, burden, self-efficacy, mastery, control, absenteeism, job–caregiving conflict, and role overload than nondementia or low dementia demand caregivers. These results suggest that clinicians dealing with patients and their families will enhance clinical care by identifying these dementia caregiver employees and intervening with psychosocial interventions known to be effective in sustaining and supporting them.

As with other stressors of old age, social support and engagement are strong modifiers of burden as are the availability of instrumental support such as homecare, respite care, and easy access to professional support. These factors are often modifiable elements in the treatment of caregiver burden when incorporated into the management of caregivers. However, beyond these instrumental psychosocial factors, management of caregivers must be integrated with therapeutic interventions to strengthen adaptive, coping skills, and self-efficacy together with enhancing skills for the management of dementia behaviors. It has been shown that fully integrated comprehensive approaches to caregivers which incorporate skills training, problem-solving training, instrumental psychosocial support, and psychotherapeutic principles can be effective in enhancing key caregiver capacities. Recent reviews of the effectiveness of psychosocial and behavioral interventions for informal dementia caregivers revealed pooled effect sizes in favor of the intervention groups on burden, depression, stress, and sense of competence.

SOCIETAL ATTITUDES AND RESPONSES

Biases about aging and the aged abound, and the older individual is confronted with them. Some of the North American perspectives on aging are quite negative—for example, older adults are perceived as no longer productive and therefore marginal to mainstream life or, because of frailty, imposing undue economic burdens on overstretched pension and public support systems. As a result, there may be a tendency to dismiss the problems of older adults or a reluctance to provide help. Perhaps not surprisingly, negative attitudes to aging, both societal and internal self-perception, are risk factors for poor health and well-being.

The effective psychotherapist of older adults incorporates these societally engendered issues into the therapy, recognizing with the patient the nature and impact of the messages and working on appropriate responses. In this role, the therapist can help to buffer the sometimes harsh messages the old person hears daily about those in their age group. A particular issue is a difference between the patient's self-perception—more youthful, involved, and competent—and the perception of younger adults who can only see and react to the apparently universal aging appearance—lost skin turgor, decreased muscle mass, gray hair, and postural change. In other words, the older person's external and age-related life issues obscure the underlying depth of feeling and identity and can delay a more complete and deeper understanding by the young of the truer self-perceptions held by the older individual. Older patients in psychotherapy often feel both misunderstood by society at large and quietly ashamed of themselves for their diminished capability and resultant helplessness, loss of purpose or role in life, or the burden they may feel they impose on others. In the presence of shame, individuals may fear new social situations and avoid them. The therapist will be most effective if these issues are articulated and explored with aging patients, helping them counter the societally induced loss of self-esteem and feelings of alienation by confronting distortions and developing techniques to defend against inappropriate stereotyping by those around them.

The COVID-19 pandemic of 2020 led to abrupt societal changes and imposed life transitions on everyone. Older adults have been particularly exposed to the implication of social distancing measures which have disrupted social networks and provoked isolation and dislocation. These changes have been widely recognized as detrimental to the mental health of older adults. Interestingly, however, studies of the impact of COVID-19 on older adults in several western countries early on in the pandemic suggested that this group may be psychologically more resilient than younger groups despite their vulnerability to more severe complications, higher mortality, disruptions to daily routines, and access to care. Similar to findings of studies in Spain, Netherlands, and Canada, the Centers for Disease Control and Prevention (CDC) survey of 5,412 community-dwelling adults across the United States in June 2020 found that mental health resilience was higher among the older adult group. In this study, participants aged 65 years or older reported significantly lower percentages of anxiety disorder (6.2%), depressive disorder (5.8%), or trauma- or stress-related disorder (TSRD) (9.2%) than young participants. It should be emphasized however, that these data do not take into account those from underrepresented minorities, lower socioeconomic groups, informal caregivers, or those with pre-existing mental health problems like depression or dementia. However, these findings are broadly consistent with studies that have shown that older adults are as resilient and perhaps more so as younger age groups.

Psychotherapy that addresses resilience can be helpful in uncovering sources of personal strength in the background and experience of the older adult patient and map them onto the current challenges. In isolation-inducing COVID-19, for example, exploring with the patient their natural kinship and friendship networks and helping them determine strategies and routines for reaching out safely and appropriately can be useful.

It is unwise to interpret old age as a risk factor in itself. For example, in this disguised but real situation, an 85-year-old man was locked down in his home because of COVID-19. He had pre-existing mobility problems and had personal support worker (PSW) home care. His wife had died 2 years previous, and his vibrant social life had come to a halt when COVID-19 shut down all social options. His therapist was especially worried about his ability to cope as this shutdown was a reprise of his prolonged quarantine with his family in the 1940s polio epidemic, crippling his father, killing his mother, and disabling him for a time. Remarkably, the prior experience, while devastating at the time, did not overwhelm or weaken him. Rather it promoted in him a sense that he had already gone through the worst and could face this new challenge.

Even the massive trauma of the Holocaust strengthened the coping and resolve of another woman, now in her 90s, who had been a hidden child when her parents were murdered by the Nazis. In her mind, the adversity of being locked down and isolated to her room in a supportive housing unit while evoking early memories of her war experiences was “nothing” compared to what her parents had gone through during transport and in the concentration camp almost 80 years before. The re-evoked memories of the Holocaust, while not easy for her to bear, were already a familiar part of her emotional landscape, and she showed remarkable resilience in the face of the new COVID-19–induced social disruption and isolation.

ECONOMIC AND ENVIRONMENTAL FACTORS

For many, old age is a time of economic and environmental change. Retirement and the many difficulties sometimes imposed by living on fixed incomes, social security, or supplements provided by children can induce real or fantasized anxiety and preoccupation about financial security. These factors can influence psychotherapy in a number of ways, for example, inducing envious transferential feelings in patients or guilty countertransference in therapists.

Financial restrictions, often real but sometimes imagined, lead to restricted social activity, feelings of isolation, humiliation, and shame, as well as uncertainty and fear of the future.

Like advancing frailty or bereavement, economic difficulties must be actively dealt with in psychotherapy. This involves determining with patients their actual financial situation, separating distortions from reality, uncovering latent meanings about financial security, and then introducing practical approaches to coping and interpretive understanding of the underlying meaning of the situation to patients.

The living accommodation is another important psychosocial variable that often changes in old age. The key element that induces psychological stress associated with moving to a new setting in old age is that it is generally a forced move, precipitated by physical or cognitive decline, economic factors, or isolation. Even more than death, the specter of abandonment to an impersonal chronic care facility is most feared by older adults. The prospect of such a move provokes various forms of abandonment anxiety, including the knowledge that this probably will be their last abode before death. This emotional reaction becomes more acute for married couples when the move necessitates the separation of the partners and placement in different settings appropriate to each one's care needs.

Moving to a long-term care facility may also generate internal conflicts associated with forced interaction with other older adult residents. Emotional responses may occur for a variety of reasons. For example, aged patients routinely express their anxiety at being confronted with the pain and disability of their age peers. In them, they see mirrored their own future and become afraid. These feelings can be powerful motivators, preventing patients from accepting realistic moves to settings where they can receive needed care. Pressing a reluctant, frail patient to accept needed help in an institution can pose ethical dilemmas for the therapist. Not the least of these is the reality that many or most of these institutions are barely adequate to the task of satisfying the needs of their residents. Concerns about the capacity of nursing homes to care for and protect vulnerable older adults were brought into stark and tragic relief by the COVID-19 pandemic. By May to June 2020, prior to vaccinations which began to protect this most vulnerable sector of the population, seniors in nursing homes accounted for a disproportionate number of deaths in North America and Europe. Canada had the bleak distinction of leading the way, with almost 80% of COVID-19–related deaths occurring in nursing homes, while in the United States, the figure was 40%. These statistics inevitably added to the struggle of seniors and their families as they weighed the risks and benefits of moving to a long-term care facility, including whether they could trust the system to watch over their safety and welfare.

Inevitably, no matter what the setting, the new resident entering long-term care will encounter severe psychosocial stressors, including some degree of loss of individual identity, regimentation to the institutional routines, and loss of privacy. Confronting these realities can be difficult not only for the patient but also for the sensitive therapist who is only too aware of the limitations of the resources upon which they must rely.

The psychotherapist of an aged patient facing environmental dislocation will be most effective if they can uncover the patient's fears and anxieties —abandonment and loneliness, shame, infirmity, pain, or death—and work toward both realistic appraisals of the future and development of skills to combat the specific feared outcome of the environmental transition.

ETHNOCULTURAL ISSUES

Culture, ethnicity, and race have a profound impact on aging, which must be understood and dealt with by psychotherapists, especially when practicing in geographical areas made up of diverse communities. For example, older adults among racial/ethnic minorities are less socially engaged, with reduced access to social groups and nonchurch-related activities. This appears to be associated with greater vulnerability to a less robust recovery from illness and mortality. Data suggest that racial/ethnic minority residents of long-term care facilities are less socially engaged than white residents, although nursing home residents, in general, have low levels of social engagement. The staff of nursing home facilities are from diverse cultures, and there may be a mismatch of cultural knowledge, values, and norms between staff and residents, which adds to isolation. In the United States, language ability may be an important factor in the mental health of seniors. For example, low English language proficiency has been associated with increased levels of depression among Mexican American older adults.

Depending on the specific community, the presence of mental illness may carry with it a profound stigma that stops both patients and their families from seeking care. These traditional cultural values are likely to be more evident in less acculturated members of ethnocultural communities. The therapist must be careful to evaluate the level of acculturation of a given patient and avoid stereotypical presumptions about cultural values, for example, assumptions about family support and filial piety.

When patients from minority ethnocultural communities do seek care, they often come with socioculturally sanctioned feelings of shame at their inability to cope with their emotional problems. Compounding the more universal problematic aspects of aging, aging members of ethnocultural communities also must deal with barriers to mental health care imposed by language- and immigration-related features, such as the feelings associated with leaving their homeland, unanticipated family conflicts, loss of status, or inaccessible spiritual support. Often, newly arrived or even well-established but poorly integrated, aged immigrants are carrying a heavy burden of isolation, for example, unfamiliar with how to travel beyond their neighborhood, unduly reliant on often overburdened family members, feeling like aliens when they may have expected to feel like respected older adults, encountering racist attitudes, or struggling with inadequate finances. While perhaps self-evident, it is crucial to the establishment of an effective therapeutic alliance for psychotherapists to convey to the patient that they are sensitive to these issues by enquiring about them in an empathic, caring, and specific manner. Therapists must be aware of the influences of their own culture on their choices, assumptions, and prejudices, guard against cultural superiority, and be willing to adopt an attitude of cultural humility and flexibility in adjusting their practice to accommodate cultural concerns. Most important is the overt demonstration to patients that the therapist recognizes them as individuals who will not be stereotyped by virtue of their culture, ethnicity, or race.

Psychotherapy and alliance building with the patient is aided when the therapist is sensitive to culturally determined reactions to and perceptions of illness and its causes, such as beliefs about traditional treatments or approaches to those who are ill, acceptance and trust of mainstream services, culturally embedded terms and expressions about illness, and values about openness versus shame with health care professionals.

Therapeutic approaches and techniques are influenced by cultural factors. Traditional cultural perspectives on aging and mental health forge the individual’s view of the determinants of mental health and, in turn, the acceptability of and trust in therapeutic interventions. To be effective, the therapist suspends preformed assumptions about the older adult's background and culture and explores in an open, inquiring manner how cultural values influence explanations for symptoms and illnesses, diagnosis, and treatment.

Therapists evaluate the degree to which culturally determined communication patterns affect therapy and adapt accordingly. These factors include four forms of communication patterns:

1. Proxemics, the study of the perception and use of personal space (e.g., Anglos are more distant, while Latinos, Black Americans, and the French want much closer stances)
2. Kinesics, the study of bodily movements—for example, facial expression or eye contact (e.g., among some Asians smiling is often an expression of embarrassment rather than mirth, and smiling may be seen by them as a sign of weakness rather than friendliness)
3. Paralanguage, which refers to vocal cues such as loudness of voice or inflections, and is easily misinterpreted (e.g., loud, rambunctious behavior is common in some groups such as Americans but is easily misunderstood as aggressive in low-volume cultures such as Japanese)
4. High–low context communication, which refers to overt, intellectualized communication (low context) versus subtle or hidden communication rooted more in situations or internalized in the person. High-context communication is exemplified by how a mildly spoken "yes" can actually mean "no" when spoken by a Filipina challenged by her superior. In this context, her "yes" is the expression of someone who is afraid to contradict her superior.

Once the patient's cultural perspectives are understood, the therapist's task becomes one of synthesizing this understanding and helping the patient integrate their traditional views with Western medical concepts (e.g., integrating the patient's view that they is suffering because of failure to honor ancestors with Western concepts of guilt). The successful, culturally competent psychotherapist will be able to translate the patient's metaphors and belief systems, understanding both their concrete and symbolic meaning. For example, understanding that because physical symptoms are acceptable while mental symptoms are not, the patient may only feel able to convey distress in physical terms such as, "I have no energy," "My heart is uncomfortable or heavy," and so on.

Decision making in many cultures is group (not individually) based, as is more common in Western culture. It is necessary for therapeutic success that the therapist recognizes the importance of family hierarchy in decision making in some cultures and maintain an authentic stance of nonjudgmental collaboration with both patient and family.

An example of cultural knowledge that can be essential to the psychotherapy of a traditional, older adult Native American, for example, is the centrality to the Native American of sacred tribal land. Tribal land usually refers to that which is occupied by an individual’s tribe prior to their resettlement. Being torn away from traditional lands was a universal experience for Native Americans, disrupting many aspects of basic culturally based practices. For example, most religious ceremonies, cultures, and customs revolve around tribal lands. Clearly, this form of dislocation, even though it occurred long ago, has had a profound effect on the personal identity of individuals, their sense of belonging in the world, their feeling of trust in those who are in power, and their sense of belonging within the wider society.

Of course, no one can hope to know all about every culture, but one basic ingredient is recognition that the older adult patient struggles with many culturally determined issues and conflicts that they may feel they have no right to speak about openly. For example, among groups who experience racism, older adults may feel uncertain about how safe it is to reveal their anger about white dominance and may view the treating doctor as a symbol of the very oppression and loss that they suffered in the past. Early in the therapy, therefore, it is useful to clearly indicate acceptance of the patient’s uncertainty and, where appropriate, actively open such issues for discussion. This can be reinforced in the first assessment when the therapist can ask about the patient’s feelings about traditional beliefs, experiences with the mainstream, including racism, the difference between their private thoughts and their public beliefs, and their sense of belonging in society and in therapy.

Psychiatrists and other therapists will be most effective if they are able to take a truly inquiring attitude toward the patient and be open to the patient’s explicit attempts to educate them. In so doing, the therapist must also take care that the patient is not taking refuge in cultural differences to explain away all emotional reactions. It is important to carefully distinguish between patients’ reluctance to reflect on and talk about themselves and true difficulties with expression. Having said this, it is also true that patients who fluently speak a language do not always use that language effectively for emotional expression. Patients may not be able to fully express their emotional state in English if it is their second language and can only convey the true meaning when they revert to their language of origin. This sometimes is relevant, especially in the early stages of dementia if language skills begin to decline slightly.

Another important cultural competence of the therapist is the ability to accurately gauge the degree of closeness or distance required by the patient. The willingness or ability of individual patients to delve into important areas such as sexuality or interpersonal conflict with family members is often colored by feelings of shame and humiliation and prohibition against discussing such matters beyond the family, some of which are culturally determined. It may be helpful to preface inquiry into these areas by first acknowledging with patients their potential sensitivity and asking how they feel about exploring such issues. In other words, it is important to address the underlying culturally determined resistance that the patient may bring to the therapy before attempting to get to the substance itself.

The effective therapist treating patients from another culture will have the capacity to match the nature of the therapy to the level of belief and sophistication about Western methods that the patient holds. For example, the idea that there are social and interpersonal origins for feeling is not universally held around the world. Moreover, the implication that early life experience affects later life development may pose culturally determined problems in the therapy.

Factors associated with immigration may have special relevance to psychotherapy. For example, often hidden but of great psychological importance, especially in refugee groups, are histories of severe deprivation and trauma associated with war, political oppression, or famine. Because psychological trauma is a function of life experience, the prevalence of psychological trauma in older adult will vary based on the life experiences of particularly aged cohorts, for example, those who lived in times of political oppression, war, or deprivation versus those who lived in relative peace and tranquility. One recent Canadian study, for example, found that 11.1% of the older adult patients presented with posttraumatic stress symptoms, but less than 2% met DSM IV criteria for full posttraumatic stress disorder. The data are clear that late-life effects of earlier adult trauma endure, but their presence must be actively sought out by the therapist, as patients frequently keep silent about their experiences and their persisting effects.

SPIRITUAL ISSUES

Frequently omitted from psychotherapy inquiry, spiritual issues may play a profound role in the lives of many older adult patients. Religious or philosophical beliefs often are a source of great comfort in enabling appropriate acceptance of change, facing aloneness, or confronting death. Aging patients may return to religion in later years, both as a source of comfort and as a social resource. Some suggest that isolated older adults may benefit from becoming more involved in religious activity. While attending to spirituality and religious needs may be important, it is often not addressed in psychotherapy, and the use of pastoral counseling is limited. Psychotherapy will be more acceptable to the patient and often more effective when it is carried out with a carefully elicited understanding of the patient's beliefs and attempts to use the strengths inherent in the patient's faith as an ally in treatment. However, the therapist must take care to deal with religion from the patient's perspective, not their own.

FUTURE DIRECTIONS

Regardless of the type of psychotherapy employed, the therapist of the aged patient must understand, acknowledge, and incorporate into the treatment the array of psychosocial factors that form the context of the patient's problems. The complex set of factors taken together is the matrix of the patient's life within which they will be supported or failed. In psychodynamics terms, this matrix may be viewed as the holding environment, the adult version of that which is provided by an infant's parents. As with children, when the holding environment fails in its supportive and enhancing functions, the individual comes under psychological stress. It is the person in their environment that is reflected in the environment within the person. Psychotherapists will be most helpful and effective when they work simultaneously with the external and internal worlds of the older adult patient.

55.4h Individual Psychotherapy

JOEL I. SADAVOY, M.D., F.R.C.P.(C), AND LAWRENCE W. LAZARUS, M.D.

Psychotherapy for the older adult has evolved in step with the evolution of general adult psychotherapy. Any debate over whether psychotherapy is as effective for the older adult as it is for younger patients is now largely resolved. The data are clear from an array of outcome studies and meta-analyses that most forms of psychotherapy are demonstrably effective in older adults treated for depression and anxiety. However, as with psychotherapy in general adult populations, there are few evidence-based guidelines that help the clinician determine which form of psychotherapy will work for a given patient. Some suggest that older adults prefer shorter-term therapies, although clinical experience indicates that there remains wide variation in what older adults want and expect from therapy. Hence, therapists will be most effective if they have an array of techniques to choose from and determine on a case-by-case basis the specific form of therapy to be used.

Overall meta-analytic reviews of randomized controlled trials (RCTs) of various psychotherapies for older adults have confirmed that the psychotherapies are generally effective. Effect sizes (ES) derived from meta-analytic studies of psychotherapy in older adults range from 0.63 to 0.78, with higher values for specific interventions, such as 0.85 for 7 studies of cognitive therapy and 1.05 for 8 studies of reminiscence therapy compared to no intervention or placebo. Life review (LR) is a more systematic technique of reminiscence (R), and data indicate it is more effective. In LR therapy for depression in older persons, the ES is more than twice that of reminiscence (LR-ES 1.28 vs. R-ES 0.52) and four times greater when well-being is measured (LR-ES 1.02 vs. R-ES 0.24).

Because of the complexity of the challenges of late life that impact the adaptation of older adults and their vulnerability to emotional disturbance and disorders, individual psychotherapy often needs to integrate other interventions into the therapeutic process. In addition to manualized models of psychotherapy in older adults, models that incorporate combinations of therapy may be necessary to address the complex factors affecting older adults' adaptation. For example, social support, sometimes mediated through the use of simple technology like the telephone and psychoeducational models, has shown positive synergistic effects with psychotherapy on depression outcomes, and systematic telephone-based psychotherapy has been effective in reducing distress in aging dementia caregivers (CGs). More recently, video conferencing for psychotherapy has become more common. However, the use of this technology has introduced complicated elements for treating older adult individuals. Data suggests that the older adult in the United States often experience internet-based interventions as unacceptable or inaccessible because of complicated technology that they have difficulty learning, lack of access to the internet, or cost considerations. Dealing with intense, emotionally charged therapeutic issues online challenges both patient and therapist to maintain a therapeutic connection without the human proximity of in-person contact. These challenges have been brought into sharper focus by the COVID-19 epidemic of 2020–2021. Because of public health restrictions on travel and face-to-face interactions necessitated by COVID-19, practitioners were forced to turn to technology to deliver psychotherapeutic services. Funding limitations, which have been a barrier to the provision of online services, were significantly eased during the COVID-19 epidemic by Medicare and Medicaid in the United States and some other jurisdictions. For example, the Canadian Federal Government provided funding to support online access to health care, and in Ontario, the publicly funded Ontario Health Insurance Plan (OHIP) has funded all live technology-enabled services during the COVID-19 epidemic. While broadened funding regulations have been introduced as temporary measures, the wide acceptance and apparent effectiveness of technology-enabled clinical service for the older adult, including psychotherapy, suggests that some measures may be adopted long term. One problem is that evidence for the effectiveness of these interventions has not caught up with the widespread use, although initial studies are promising. For example, a recent systematic review has found that online cognitive-behavioral therapy (CBT), problem-solving therapy (PST), and behavioral activation are both acceptable and effective for the older adult.

Psychotherapies are effective treatments for depression in late life and may sometimes be considered a first-line intervention. Studies comparing the efficacy of various individual therapeutic approaches for depression in geriatric outpatients (e.g., cognitive-behavioral, interpersonal, problem-solving, reminiscence and LR, and psychodynamic psychotherapy) have not yet been able to demonstrate the superior efficacy of one approach over another. At the Palo-Alto V.A., for example, a comparison of cognitive, behavioral, and brief psychodynamic therapy for depressed older adult outpatients found comparable remission ratios (53% had remitted after about 18 sessions). At 2-year follow-up, 77% of those whose depression had initially remitted were still depression free. The majority of patients who did not respond to the initial treatment remained depressed at the 2-year follow-up despite continued treatment. An important variable limiting reliable generalizability of the effectiveness in depression of the most well-researched psychotherapies in the older adult, CBT and PST, is the fact that these studies have generally been conducted on young-old cohorts which are well white and well educated.

Having said that, data suggest that older adults prefer psychotherapy to medication for depression treatment. Depression is often comorbid with other medical comorbid conditions, and psychotherapy has shown effectiveness in depression with various comorbidities, including chronic obstructive pulmonary disease, heart failure, Parkinson disease, and stroke, among others. Similarly, evidence suggests that psychotherapy can be effectively delivered in a variety of health care and social settings. While choosing specific forms of psychotherapy for individual patients of any age remains a refined and somewhat unreliable clinical skill, choosing an intervention for the sometimes complex presentations of the older adult requires even more care since it must take into account psychiatric, medical, functional, and cognitive status, together with the settings in which depression is likely to present, for example, long term care, hospital wards, and community health care centers.

For more severely depressed outpatients, a combination of psychotherapy with an antidepressant may be more effective than either alone. Interpersonal psychotherapy (IPT), for example, has shown effectiveness in enhancing social adjustment when used in combination with an antidepressant. Even here, however, initially, positive research outcomes have been called into question by more recent data. One problem in interpreting the data is that the variables of psychotherapy, such as frequency of intervention, are not always standardized from one study to another, limiting the generalizability of specific studies.

Creative, neurobiologically informed behavioral psychotherapeutic interventions that require little training and are readily delivered in community settings show promise. An example is Engage, an evidence-based, manualized behavioral intervention that promotes engagement in previously meaningful, rewarding activities that may have been impeded by depression through simple interventions. Trained Engage therapists use “reward exposure” to promote the activation of positive valence systems, dysregulation of which may promote depression through increased negativity bias, apathy, and emotional dysregulation. In each session, similar to PST methodology, patients prioritize two to three activities that are meaningful to them, brainstorm ideas on how to pursue them, and make a concrete implementation plan. Data suggest that this approach is effective, readily learned, and adopted by clinicians of various types in community settings.

Meta-analysis of evidence-based psychosocial therapies for anxiety has revealed support for CBT, cognitive therapy, relaxation training, and supportive therapy both for self-reported as well as diagnosed anxiety in older adults at post-treatment. One comprehensive analysis reported an overall mean ES for treatment versus no treatment or placebo control of 0.55, just above the median (0.5), providing some, although not robust, support for psychological treatment of late-life anxiety.

The strongest support is for CBT for generalized anxiety disorder (GAD) but is weaker for subjective anxiety, where relaxation training has demonstrated more efficacy especially when practiced long term. Meta-analytic study shows support for the effectiveness of CBT for GAD but CBT does not clearly emerge as a better treatment when compared to active controls.

Age-related brain changes probably affect the response of older adults to psychotherapy although empirical data are modest. For example, reduced bilateral cortical thickness may be a marker of individuals at higher risk for poor response to psychotherapy.

In this section, the authors review the history of, and theoretical basis for, psychotherapy with the older adult, give brief descriptions of various therapies with illustrative clinical vignettes and suggestions for future research.

HISTORY

Modern psychotherapy began with Sigmund Freud’s attempt to construct a universal model of understanding human behavior. In the prebiologic era of psychiatric treatment, psychoanalytic theory formed the basis for most psychotherapeutic interventions. Unfortunately, Freud held a particularly gloomy but highly influential view of the potential for the psychoanalytic treatment of patients over the age of 50. He believed that there was too much material to be dealt with and that the older adult had inelastic mental processes and hence were not educable. These ideas produced inordinate pessimism about the potential for psychological change in older adults. As the psychotherapies matured and began to be applied to a broader range of patients, therapists came to recognize that age per se does not preclude therapeutic change. Indeed, in the 1950s and 1960s, several analysts wrote enthusiastically about their positive experiences in treating older adult patients. In retrospect, this enthusiasm resulted from the treatment of generally vigorous older adult patients who were good candidates for analytically oriented psychotherapy.

THEORETICAL ISSUES

Effective psychotherapy, at a minimum, appears to require a strong, early, working alliance regardless of which specific psychotherapy technique is used. The working alliance is commonly understood to be agreement on the goals and tasks of therapy in the context of a positive affective bond between patient and therapist. Older adults, not unlike younger patients, vary in their expectations and understanding of psychotherapy. They often come to psychotherapy with general wishes to feel better but uncertain what to expect. As with younger patients, the alliance in psychotherapy is enhanced when: the therapist steps back with the patient to inquire about the nature and form of the problems; helps the patient define agreed-upon goals for therapy, and articulates them clearly such as reduction of anxiety symptoms or improved relationship with a significant other; there is a personal bond between therapist and patient, in which the patient views their therapist as caring, understanding, and knowledgeable; both patient and therapist agree on the means to achieve goals.

Alliance is further strengthened when the therapist implicitly or explicitly conveys to the patient their understanding and knowledge of the age-related tasks and challenges facing the patient. There are many models for framing this understanding, depending on the type of therapy being used, but at the root, each model makes use of common themes now understood to underpin the adaptational challenges of those negotiating the geriatric phase of life.

A major developmental task of aging is finding restitution for the inevitable biopsychosocial losses associated with this stage of the life cycle. Therefore, loss is one of the most prominent issues discussed by older adult patients. For many, it is the cumulative effect of multiple repeated losses, before sufficient time has passed for mourning and resolution, that is so devastating. The older person struggles to maintain ego integrity and a sense of purpose in life at a phase of the life cycle often characterized by diminishing coping resources, increasing self-doubt, and the onslaught of assaults and challenges to self-esteem and a positive self-image. The magnitude of an older adult person's reaction to a loss depends, to some degree, on the amount of pride and emotional investment in the lost function. Beyond lowered self-esteem, older adults experience life changes that can damage their sense of security and safety. For some, the world becomes uninviting and dangerous, particularly if they have encountered real events such as falls, personal attack, or inaccessible help at a time of need.

Perhaps counterintuitively, fear of death is not as prominent in the older adult as in younger adults and hence is not a major theme in geriatric psychotherapy. Clinical experience suggests that other fears especially focused on health concerns, incapacitation, memory loss, pain, abandonment, and helplessness are more evident. For example, in one psychotherapy study cohort of seniors over age 60, reasons for seeking treatment were depression related to interpersonal relationships, health conditions, grief/loss, finances, housing, and challenges due to executive dysfunction.

Self-worth, security, and independence depend in part on the individual's ability to maintain physical capacities. Beyond obvious challenges posed by physical illness or decline, impairment of important psychological functions becomes pronounced when frailty or illness forces restricted function and imposes a new, different, and often unacceptable self-image and personal identity.

Psychological adaptiveness in old age varies widely. Vulnerability to states of depleted self-esteem, insecurity, fear, or anxiety is heightened when an individual cannot adapt flexibly and is too wedded to maintaining or retrieving that which must be relinquished. Problems of psychological adaptation and diminished self-esteem occur in late life because of such factors as overdependence on social or work roles, overemphasis on the maintenance of control and mastery in all situations, and unresolved problems with self-esteem arising from earlier developmental stages. Difficulties with self-esteem may be rooted in maladaptive, unmodified beliefs; unconscious issues such as dependency conflicts; or interpersonally generated psychological reactions like unresolved grief.

The majority of older adult persons adapt quite well to the challenges imposed by negative societal stereotypes about aging and the losses noted above that threaten to erode self-esteem. Several psychological self-protective mechanisms help to maintain a positive self-image, such as focusing on past successes, discounting messages that do not fit with lifelong self-concepts, refusing to apply general myths and misconceptions about aging to the self, and choosing to interact with those who provide pleasurable self-esteem–enhancing experiences. Some selectively screen out unwanted perceptions such as those that challenge impaired cognitive abilities. While often adaptive and self-protective, such selectivity may also distort reality and promote maladaptive denial.

GENERAL TECHNIQUES

In the initial interview, the psychiatrist explores the major reason the patient has come for the interview and is active and empathic in exploring patient and family resistance to therapy. The patient and family are asked to bring with them all currently used prescription and over-the-counter medications. Psychotherapy with the older adult can only be successful if it is integrated with effective management of relevant somatic factors affecting adaptation and emotional responses. Hence, careful attention is paid to previously overlooked medical problems and medication adverse effects that may contribute to current psychiatric signs and symptoms.

The older adult patient is usually interviewed individually before important information and concerns are obtained from the family with the consent of competent patients. Older adult patients respond positively to the therapist's listening, empathic, and encouraging attitude. Some patients like to sit close to the therapist and may welcome such expressions of spontaneous warmth as a natural touch on the patient's arm. However, the therapist evaluates each patient's sensitivity to intimacy and does not assume that familiarity is welcome just because the patient is old. Inquiring about how the patient has successfully coped with adversity in the past helps to recall effective coping strategies and offers hope that current stresses and losses can be similarly overcome.

Psychologically less sophisticated patients, who are accustomed to talking about their physical complaints when visiting a physician, initially may feel more at ease if the therapist begins with a medically oriented focus. The therapist may then shift the focus to psychological and social problems.

In general, the therapist of the older adult patient is more active, engaging, supportive, and flexible than with younger patients. The therapist is knowledgeable about the normative, age-related changes that occur in the psychological, cognitive-intellectual, and social life of older people; geriatric medicine; psychopharmacotherapy; family therapy; and community resources. In both office and hospital settings, it is especially useful to work with a mental health colleague, such as a social worker, who is knowledgeable about family therapy and community resources. Patients must feel that they have obtained something from the initial interview (e.g., empathic understanding; hopefulness) to increase the likelihood that they will return for subsequent sessions. Telephone reminders to selected patients or family members in advance of the next appointment impart the therapist’s interest and improve patient compliance. Older adult patients, particularly the frail and dependent, may hesitate to express any negative reactions or doubts about therapy. The therapist might wonder out loud whether the patient may find it difficult, for a variety of reasons, to return for a second visit. Such exploration increases the likelihood that therapy will continue.

Realistic, explicit treatment goals are negotiated with the patient and, as appropriate, family. If treatment goals are overly ambitious, both patient and therapist may experience frustration and disappointment. Many older adult patients, whether consciously or unconsciously, have a specific treatment goal in mind, which once accomplished, leads them to terminate treatment.

SUPPORTIVE PSYCHOTHERAPY

More frail patients, such as those who are cognitively impaired or chronically ill, may require such psychotherapeutic techniques as support of healthier defense mechanisms, ventilation, advice, help with acceptance of diminished capacities, and increased dependency needs. Rather than trying to achieve intrapsychic change, the therapist strives to improve and refine the environment to the particular needs of the patient. For example, the therapist may help the family to arrange a more caring, nurturing environment and assist them to become better CGs.

The patient’s life history and psychodynamics (obtained from the patient or family members) enable the therapist to institute specific supportive therapeutic strategies.

An older adult woman with progressive cognitive impairment and lifelong personality traits of dependency and passivity is anxious and depressed about entering a nursing home. She may adapt well to the home if assigned to a roommate who is nurturing and protective.

Alvin Goldfarb has described a brief, supportive therapy technique for institutionalized, cognitively impaired patients. The therapist improves patients' foundering self-esteem, sense of control, and safety by permitting them to develop an apparent special relationship with the therapist, who is perceived as benevolent and powerful. The patients believe they have some control over the benevolent physician. This is accomplished in small, subtle ways. For example, the physician may elicit the patient's preferences for the frequency of sessions, daily timetables, or diet. Then in a realistic or symbolic way, the therapist acquiesces to the patient's wishes while maintaining a quiet caution about being perceived as being unduly manipulative.

INTERPERSONAL PSYCHOTHERAPY

There are not a lot of data supporting the efficacy of IPT in older adults. However, what there is, suggests it is useful as either a primary intervention for depression and possibly as an adjunct to antidepressants although this latter data are inconsistent.

Nevertheless, older adults often have to cope with loss of friends and family, to adapt existing social skills to changing life circumstances, and to resolve conflict with significant others, especially adult children. Hence, a therapy that helps the older patient cope with and resolve interpersonal problems would seem well suited to older adult patients. Recent cross-sectional study data in older adults confirmed that loneliness is a significant risk factor for depression in both men and women although especially so for women. Interestingly and perhaps counterintuitively, social network size was not associated with the risk of depression, although this is consistent with other findings, that is, it is the level of perceived intimacy and social support that is most critical rather than the overall size of the social network.

IPT is a time-limited (usually 16 weeks), manualized psychotherapy that focuses on one or two interpersonal problems, such as the death of a family member. It has been adapted and studied in the acute, continuation, and maintenance treatment of late-life depression.

In a series of controlled studies at the University of Pittsburgh, 79% of older adult outpatients with major depression who were treated in the acute and continuation phases with a combination of IPT and nortriptyline achieved full remission. Over the subsequent 3 years, 80% of the patients with recurrent major depression who had remitted and who continued on combined treatment, compared with 10% who received placebo, were still in remission.

LIFE REVIEW OR REMINISCENCE THERAPY

There is considerable empirical support from many RCTs of the efficacy of individual LR and reminiscence therapy for the treatment of depression, compared to no treatment control groups although support for group intervention is not strong. Along similar lines, there is some evidence that autobiographical memory practice can reduce symptoms of depression when compared with “usual care.”

Reminiscence is characterized by the progressive return of memories of past experiences, especially those that were meaningful and conflictual. It is theorized that reviewing the past helps the patient find greater meaning in the present. To varying degrees, older adult patients in therapy reminisce about the past, search for meaning in their life, and strive for the resolution of past interpersonal and intrapsychic conflicts. LR therapy is the therapeutic promotion of reminiscence by systematically enhancing this reminiscing process making it more conscious and deliberate. The therapist may guide the process by encouraging the patient to write or tape an autobiography. Techniques include reunions with family and friends and looking through memorabilia such as scrapbooks or picture albums. This technique has been reported to resolve old problems, increase tolerance of conflict, relieve guilt and fears, and enhance self-esteem, creativity, generosity, and acceptance of the present. Perhaps obvious is that the effectiveness of reminiscence interventions requires sensitivity to the individual and sociocultural history of older adults, which may be obscured for younger therapists by the passage of time or unfamiliarity of therapists with the backgrounds of immigrant older adults. Culturally appropriate reminiscence techniques have shown efficacy for symptoms of depression, anxiety, and low self-esteem among Taiwanese older adults.

Some authors have cautioned about possible negative consequences of encouraging LR, particularly for a depressed patient with obsessive tendencies or life histories filled with multiple misdeeds not amenable to a positive review. Evoking memories in patients who have suffered massive trauma or whose lives have been seriously affected by deprivation, overwhelming abandonments or humiliation will be emotionally challenging for patients, and therapeutic technique is directed to providing an environment of safety and trust so that the evoked emotion can be contained, modulated, and perhaps reframed to enhance self-acceptance.

COGNITIVE-BEHAVIORAL THERAPY

Older adults are a heterogeneous population. There is no consensus on how much adaptation is necessary for the CBT technique for older adults. However, it is probable that when frailty, sensory impairment, or cognitive decline is present, therapy will be facilitated if some adaptations are employed. For example, with some older adults, the therapist is often more active with a focus on here-and-now issues. The pace of therapy is sometimes slower than with younger adults, and when appropriate, the therapeutic alliance may be enhanced by permitting the patient to adopt a senior teaching role with the younger therapist. To compensate for specific deficits such as hearing loss or cognitive slowing, information may be presented in different modalities, such as written material or taped sessions for the patient to take home. Homework has been found to be feasible with many older adults and helpful to the process, including the use of formal thought records. With older patients, material may have to be reviewed more often, and termination is often managed gradually rather than abruptly.

There is some evidence to suggest that CBT is most effective for older outpatients with mild–moderate depression who are relatively healthy with high motivation for treatment and absence of a personality disorder. These characteristics are not unlike those of candidates for psychodynamic therapy and IPT.

PROBLEM-SOLVING THERAPY

Four RCTs investigated the effectiveness of PST for older adults. Three found that PST was better than other therapies and better than no treatment although not all trials are positive. There is some indication that PST is especially useful for depression associated with executive dysfunction where problem solving and decision making may be particularly impaired. A large comparative trial of PST and supportive therapy found that the more structured and focused intervention of PST versus a less structured supportive method was more effective for treating late-life depression associated with executive dysfunction.

PST has been adopted for use in a variety of disorders and older adult populations with demonstrated effectiveness. It has been shown to be effective in reducing symptoms of poststroke apathy compared to placebo, late-life major depression compared to supportive therapy and reminiscence therapy, minor depression and dysthymia compared with paroxetine and placebo, and vision-related quality of life in patients with macular degeneration.

PST is a brief solution-focused intervention that draws on methods commonly employed in other modes of structured therapy such as CBT or IPT, that is, direction and coaching, hierarchical lists created, homework assigned, relating problems encountered to evoked emotions, situational analysis of antecedents and precipitants for the problem, and patient-generated solutions guided by the therapist are core to the method. Problems can range from major adverse life events, such as bereavement or illness, to everyday coping such as transportation, banking, or shopping. Once a problem is identified and its determinants are specified, a brief list of the pros and cons of potential but realistic solutions is generated by the patient and therapist taking into account the focal nature of the therapy and the time constraints of the brief format. Patients with mild cognitive impairment can utilize PST if they retain sufficient cognitive capacity to absorb the method and retain key elements from one session to the next. They may require additional supportive strategies, such as written notes, memory devices, environmental adaptations, and CG involvement.

PST may be most effective when delivered face to face either individually or in group formats but other acceptable and feasible methods of PST delivery have been shown to be effective for harder-to-reach patients, such as Internet-based therapy for depressed home-care older adults. Improvement in quality of life and a reduction in anxiety symptoms have been demonstrated through the use of videophone in hospice CGs.

PST has been widely adopted for use with informal CGs of those with dementia improving coping skills, self-efficacy, and depression. Frontline workers dealing with patients with dementia and their families in the community are often overwhelmed by the complexity of problems they must address during relatively short interventions. When professional workers in the community are trained in PST, it has been shown that, compared to a control group of CGs in standard care, PST training helps them organize their approach to complex problems. This, in turn, appears to enhance their ability to help CGs, thereby significantly improving the capacity of CGs on key measures of function and emotion, such as coping, mastery, and competence, while significantly reducing emotion-oriented coping, burden, and stress.

BRIEF (TIME-LIMITED) PSYCHODYNAMIC PSYCHOTHERAPY

Brief or time-limited psychodynamic therapy can be considered for older adult patients with clearly defined, age-related problems that can be expected to resolve within a brief period of psychotherapy, such as an adjustment disorder, unresolved grief reaction, or new-onset anxiety disorder. Setting a time limit at the beginning reinforces the patients' confidence in their ability to resolve problems within a circumscribed period of time, focuses and accelerates the therapeutic process, diminishes the fear of dependency, and accommodates limited financial resources. Brief therapy uses the therapist's psychodynamic understanding of the patient and the patient's transference to clarify and help resolve the patient's emotional reactions to current life stress.

In a pilot study of the process and outcome of brief psychodynamic psychotherapy of patients with an adjustment disorder with depressed mood, the women showed greater improvement and were more active and assertive than the men, who tended to become more dependent on the therapist. The patients used the therapist to validate competency and normalcy, which helped to support and restore feelings of mastery and self-esteem. Symptomatic improvement often exceeded the achievement of insight or self-understanding.

INSIGHT-ORIENTED PSYCHOTHERAPY

While studies of dynamic psychodynamic therapies are relatively sparse in number, several RCTs of psychodynamic therapy (including brief dynamic therapy) for older adults have shown that it is an effective treatment for depression comparable to other forms of therapy, such as CBT in one head-to-head trial. Overall, data suggest that about 70% of people who had received dynamic psychotherapies were in remission at a 2-year follow-up, broadly consistent with meta-analytic data on the overall efficacy of psychotherapy in older adults. A rich array of both earlier and recent literature describing successful clinical cases of psychotherapy with the older adult convincingly supports empirical data and the position that, for appropriately selected cases, age per se does not interfere with the effectiveness of psychodynamic therapy, including psychoanalysis.

The selection of patients and the basic approach to insight-oriented therapy for older patients who are physically and cognitively intact is largely the same as that for younger patients. Appropriate patients have the ability to form a therapeutic alliance, the capacity for introspection and to mourn losses, and the motivation for change. Older patients may be particularly suited for this therapy given their appreciation of the finitude of life, increased tendency toward introspection, and a more philosophical view of themselves and life.

During longer-term psychotherapy, the condition and circumstances of the older patient evolve and change. The development of physical illness may require a medical referral, collaboration with family members, or advocacy on behalf of the patient for community and other support services. Such active intrusions into the patient’s real-life problems are not commonly dealt with by psychodynamic therapists, but when treating older adult patients, techniques often need to be adapted to their changing needs. Therapists are most effective when they learn to integrate different therapeutic modalities while maintaining a psychodynamic focus on the therapeutic relationship, the transference, and the goal of inner conflict resolution. Indeed, the necessity to effectively integrate different modalities of treatment is one of the hallmarks of the therapist’s flexibility necessary to treat and manage the evolving therapeutic issues of older adult patients.

MULTICOMPONENT PSYCHOTHERAPEUTIC INTERVENTIONS FOR FAMILY CGs

Older adults are commonly confronted with undertaking caregiving roles with spouses who develop dementia. It has been estimated that 75% of community-based caregiving is provided by informal family CGs. In the United States, most of these family CGs are older female spouses who are disproportionately vulnerable to the well-established negative effects, both physical and psychological, of dementia caregiving leading this group to be so-called hidden or invisible second patients. These dementia CGs must cope with the emotional and practical problems posed by a progressive, untreatable disorder that gradually erodes the fabric of the relationship with their care recipient (CR), causing attendant emotional loss and grief. Over the years, the CG must learn to navigate a new, unfamiliar, and unwelcome lifestyle, increasingly trapped in a role that forces them to cope with an illness that induces behavioral and psychological distress as a disturbance in the CR, alters their behavior and personality, and impairs independent functioning, capacity for communication and decision making. Attention to the psychological morbidity of CGs is clearly important, both to prevent care breakdown and institutionalization of the CR and to sustain the CG.

Intervention methods for supporting the health and well-being of dementia CGs have included education and psychoeducation, peer-support groups, CBT, and family counseling. A recent review concluded that there is support for the clinical and cost-effectiveness of multicomponent programs. CBT and multicomponent intervention outcomes for CGs with depressive disorders were positive, with a large ES.

Group and family-focused psychotherapy have been shown to be effective for dementia CGs incorporating psychoeducation, cognitive reframing, communication skills training, and professionally led group interventions. Examples of evidence-based, successful, scalable multicomponent programs are the Canadian program called CARERS, an acronym for **C**oaching, **A**dvocacy, **R**espite, **E**ducation, **R**elationship, and **S**imulation, and the New York University Caregiver Intervention (NYUCI).

CARERS is a manualized, integrated multicomponent group psychotherapeutic, skills-training intervention demonstrated to be an effective intervention for improving coping, mastery, depression, and burden in family CGs. The psychotherapeutic group intervention is designed to systematically address three key areas of CG need: problem-solving, communication, and behavioral management and the emotional impact of dementia caregiving. Following an in-depth intake assessment, each CG participates in eight weekly 2-hour closed group sessions of four to six CGs led by a trained mental health clinician. A predetermined agenda structures the outline of each group while the content of each group is determined by the CGs, based on an initial go-round check-in to elicit current caregiving problems and challenges and emotional reactions and foster group cohesion. In sessions 1 through 4, CGs are taught a form of problem-solving therapy adapted for dementia CGs; communication and behavioral management are addressed in sessions 5 to 8. Specially trained standardized patients participate with each CG in tightly controlled, live therapeutic simulation interventions during which the group therapists coach CGs and lead group interaction focused on the observed emotional consequences of communication breakdown and isolation. Group psychotherapy principles inform all aspects of CARERS to foster the presumed curative factors of group psychotherapy, including ensuring safe emotional expression, instillation of hope, universality and reduced isolation, imparting information, altruism, interpersonal learning, and group cohesiveness. Since its inception in 2009, more than 300 therapists have completed a systematic, manualized course of face-to-face and e-learning training. All aspects of group intervention and training have been adapted to be delivered both face-to-face and live online. CARERS is demonstrably scalable and has maintained effectiveness and fidelity when disseminated to multiple sites in Canada and the United States. It is the core intervention program for the Ontario Ministry of Health-funded program called Enhancing Care for Ontario Care Partners.

The NYUCI for CGs is a well-researched, evidence-based, demonstrably effective program comprised of a detailed intake assessment followed by two individual and four family counseling sessions, support group participation, and telephone counseling for both the primary CG and family members. Postintervention phone or email support is provided indefinitely to address evolving changes as dementia progresses. Several studies have shown its effectiveness in reducing CG depression and delaying nursing home admission.

OTHER THERAPIES

Mindfulness-based cognitive therapy (MBCT) and mindfulness-based stress reduction (MBSR) have been increasingly used interventions for the management of anxiety, depression, and stress-related symptoms. Recent data suggest that, when compared to waitlist controls, MBSR may be effective in older adults, although the quality of studies is often low. In a province-wide intervention in Ontario, Canada, for family CGs of persons with dementia living at home, a manualized telemedicine version of MBCT has been successfully modified for delivery online and is currently in the early stages of service rollout. Participants, many of whom are older women, value the accessibility of the online telemedicine format and readily adopt the intervention. A small preliminary feasibility study has shown that the intervention is acceptable and effective in improving self-compassion and coping among CGs when compared to usual care controls.

CLINICAL ISSUES

Indications for Individual Psychotherapy

Older adults are a heterogeneous population. The continuum ranges from the normative or healthy older patient whose overall functioning is retained to the frail older adult patient. Five categories are normative older adults; normative older adults in crises; independent frail older adults; dependent, physically frail older adults; and dependent, cognitively impaired, frail older adults. Indications for various modalities of individual therapy are strongly influenced by the position of the patient on the normative–frail continuum. Moreover, because capacities change over time, therapeutic approaches for a given patient may also need to change.

With advancing age, a crisis is frequently the stimulus for seeking out psychiatric care, often initiated by a family member. A small qualitative study found that common reasons for older adults seeking psychotherapy included depression related to interpersonal relationships, health conditions, grief/loss, finances, housing, and challenges due to executive dysfunction, that is, mild cognitive dysfunction.

Individual therapy during crisis focuses on mourning for lost important relationships or personal capacities and working through conflicts over separation, redirecting energy to more realistic goals, redefining relationships, especially with regard to accepting appropriate dependency and reestablishing or developing appropriate strategies to enhance mastery, sense of control, and self-esteem. Family education about ways of helping the impaired older adult is of critical importance. Psychotherapy during a crisis is often integrated with medication and environmental therapies. Problem-solving techniques, brief IPT, and CBT are useful approaches during crises, although longer-term supportive or psychodynamically oriented therapy may evolve.

Behavioral techniques using operant behavioral conditioning have been applied to a wide range of target symptoms in chronically ill older adult patients, including incontinence, pain, insomnia, wandering, socially inappropriate behaviors, reduced level of activity and participation, toileting, bathing, and feeding. Environmental cues are manipulated to increase, decrease, or shape behaviors. These techniques are useful for institutionalized and frail older adult patients to reduce the excess disability that often accompanies dementia. An ABC approach to behavioral management of disturbed behavior may be useful. This technique includes accurate neuropsychological evaluation; defining specific measurable and observable behavior for modification; determining the antecedents (A) to the onset of the disturbed behavior and systematically recording them; recording the type, frequency, and duration of the baseline (B) conditions; tailoring a treatment program (A and B) to alter the behavior, which includes CG counseling, the introduction of reinforcing, and extinguishing techniques, that is, consequences (C); instituting environmental changes and psychotherapy to assist CG; and program evaluation. A major deficiency of behavioral interventions is their labor intensiveness and the need to maintain the program. Once the interventions are withdrawn, behaviors tend to return to pretreatment levels in these institutionalized patients. Cognitive-behavioral interventions in long-term care settings, while often effective when introduced by a consultant, generally fail if the consultant leaves. Frontline staff in these settings usually lack the training to sustain sophisticated cognitive-behavioral programs on their own.

Various forms of individual psychotherapy have shown therapeutic value for states of bereavement. Bereavement can lead to chronic states, sometimes called complicated or prolonged grief, which is characterized by the persistence of acute grief symptoms complicated by cognitive, emotional, and behavioral symptoms. Complicated grief is common, found in 9% of bereaved older women. Psychotherapeutic interventions are particularly effective for bereavement complications such as chronicity, depression, or anxiety disorders. Most interventions include some education, support, attention to the relationship with the deceased before death and as it has changed since, and supportive assurances of “normality” for bereaved individuals who need to be reminded that their feelings and experiences are not deviant or abnormal. Complicated grief therapy (CGT) has structured this process and includes grief monitoring, imaginal and situational revisiting (promoting memory and using aids such as pictures or situations), imaginal conversations, building personal emotional and instrumental supports, defining and planning personal aspirations and opportunities for self-care, and promoting positive emotions. RCT data suggest that, when compared to IPT, CGT may be highly effective for the older adult.

Psychotherapy of various types has been recommended for the treatment of anxiety disorders. Preliminary data suggest that CBT can be quite effective in older patients with panic disorder and may thus be considered as an alternative to pharmacologic treatment for selected patients or as an adjunct to pharmacologic treatments when patients have behavioral symptoms that can be targeted.

Psychotherapy has shown some value in the management of older adult patients struggling with alcohol abuse. The inclusion of cognitive-behavioral training that addresses themes of self-advocacy, self-esteem, and relapse prevention may aid recovery.

Individual psychotherapy is often helpful in the treatment of sexual dysfunction. For example, premature ejaculation usually responds readily to sex education, reassurance, and sex therapy techniques practiced at home alone or with a cooperative partner.

Limitations

Older adults are underrepresented in psychiatric outpatient clinics (2% to 4% of patients seen) and even more so in private psychiatric practice. Older patients are often not referred for therapy, possibly because primary care physicians are not fully aware of its effectiveness in the age group. Overall a minority (25% in one study) of depressed older adults receive psychotherapy, but even of these, only one-third got consistent, ongoing therapy. Young–old, more highly educated older adults are more likely to receive psychotherapy.

The application of psychotherapy, therefore, appears to be limited by the willingness of practitioners, both psychiatric and primary care, to use it for older adult patients. Completion of a series of regular therapy sessions, whether short or long-term, is often limited by practical considerations such as difficulties with insurance and personal finances, transportation, or weather.

Raised in an era when shame was associated with psychiatric problems and treatment, some older adult persons feel embarrassed and indignant when their physician or family suggests consultation with a psychiatrist. Many older adult persons, as well as health professionals, believe that depression and anxiety are expected concomitants of aging or routinely attribute abnormal psychological states to physical illness. The symptoms themselves, such as depression, apathy, and hopelessness, prevent older persons from seeking treatment. Patients whose ethnoracial backgrounds differ markedly from that of their therapist may have quite different notions and expectations about a visit to a psychiatrist. Many cultures view mental disorders as shameful. Individuals may fear damage to their families' reputations. For example, older adult patients from some ethnic backgrounds have expressed fear that their grandchildren may be less marriageable if there is a mental illness in the family. Beyond cultural barriers, other access barriers limit care for these groups, including language incompatibilities, lack of knowledge of where to obtain psychiatric services, economic issues, a tendency to seek care only after a crisis, and fragmented, difficult-to-access mental health care services.

Adult children of an aging parent may minimize the parent's psychiatric symptoms, be ambivalent about assuming a parenting role, and may share their parent's negative attitudes toward psychiatry. All these barriers result in impaired access to care, poor compliance with medication and psychotherapy, and a high dropout rate.

Strategies to overcome these formidable barriers in the very first session include active exploration of patient and family resistances to treatment, discussion of how ethnic differences between therapist and patient can interfere with treatment, ambivalent and negative attitudes about psychotropic medication, and encouraging the patient to share reactions to the first session. If the therapist intuitively suspects the patient is resistant to treatment, active inquiry about problems that may interfere with subsequent sessions, such as shame or practical issues like transportation, are explored. It is important that the patient feels that something has been achieved in the very first session. In this way, the seeds of the therapeutic alliance are planted with both the patient and family in the initial visits. Even for the very impaired, depressed patient bereft with hopelessness, conveying hope and a willingness to help can facilitate the beginning of a therapeutic relationship.

Complications

Whatever the form of psychotherapy, the course may be complicated by issues of transference and countertransference. The patient's feelings about therapy will be influenced by education, socioeconomic status, culture, and ethnicity, which can restrict or enhance the impact of treatment.

Transference is age-independent (of both patient and therapist), the determinants stemming from the timeless unconscious. However, developmental theory expands the traditional perspectives by demonstrating that transference derives not only from significant infantile experience but also from internalized objects encountered in adult life, for example, a spouse or a child.

While there are no age-specific transferences, the psychodynamic impact of life experiences during old age may increase the emergence of certain forms. For example, frailty leads to dependency conflicts and fears of abandonment, emotions that can easily evoke parental transference reactions toward the health professional derived from the reactivation of the patient's need for a protector (parental figure). This form of transference emerges readily in dependent, institutionalized, or otherwise isolated patients, even when psychotherapeutic contact is relatively brief and intermittent. Bereavement, especially of a spouse, or other loss (e.g., sexual capacity) may lead to an eroticized spousal transference to the therapist in which the patient unconsciously relates to the therapist as an erotic love object who becomes a fantasy substitute for the lost object.

Reverse transference describes a phenomenon of geriatric psychotherapy in which the patient experiences and relates to the therapist as a child and takes a parental role toward the therapist in the treatment dyad. Therapists may experience this transference interaction as demeaning or patronizing and feel uncomfortable with the seeming reversal of dominance. Young therapists may find this especially challenging. It is generally a transient phase of therapy that defensively protects the patient from deeper levels of transference-based affect associated with conflicts over dependency.

Somewhat different is filial transference, in which patients deal with the therapist as one of their own children, enacting such unconscious conflicts as rage for not fulfilling wishes for caring or guilt derived from earlier failures in the parental role.

Countertransference responses of therapists are often intense in the treatment of older adult patients, sometimes blocking the therapist's willingness to engage the patient in individual psychotherapy. The complexity or chronicity of problems of late life may lead therapists to be unduly concerned that older patients will become dependent on them and engender some therapists' reluctance to embark on treatment for fear of the patient's dependency. Similarly, it is not uncommon for younger therapists to avoid treating older adults because of their anxiety over having to deal with frailty or decline in older patients. Uncertainty about their ability to help the older person may induce feelings of guilt or anxiety in the therapist and lead to withdrawal from or avoidance of the provision of psychotherapy.

Engaging at an emotionally deep level with older patients becomes even more challenging for therapists who are struggling with problems that echo those of their patients. This dynamic has been brought into stark focus during the recent COVID-19 pandemic as patients and therapists alike have been forced to confront the emotional, psychological, and practical challenges of isolation, social distancing, shutdowns, restrictions, and anxieties. For example, a therapist whose practice is focused on working with spouses struggling with the emotional impact of their partner's dementia went through a period when they were unable to take on patients that reminded them of their mother, who was devastated by the evolving dementia of the therapist's father. Supportive supervision helped the therapist separate their own feelings from their patients' and gradually enabled them to reengage effectively.

Less experienced therapists may initially doubt the applicability of their skill to older adult patients, thus reinforcing preexisting uncertainties about the mastery of their craft. The patient's frailty sometimes induces especially strong withdrawal from using psychotherapy because therapists are unwilling to encounter and confront their own hopelessness and fears of abandonment or mortality. Some therapists withdraw because of fear of being engulfed by the patient's demands and dependency. These factors may be compounded by the added therapeutic burdens of working at a slower pace and dealing with sensory deficits and cognitive decline.

Countertransference parallels transference reactions in that therapists may develop strong urges to rescue the patient and do too much, reactions that may derive from unresolved guilt toward their own parents.

Therapists must deal within themselves with the repetitive need for therapy to focus on mourning and acceptance of loss. This is in contrast to the more hopeful perspective of ego development and mastery, which is common in psychotherapy of younger adults and easier for therapists to deal with. Treating older adult patients holds the danger that helpless anxiety or despair may emerge in therapists who have not successfully dealt with their own issues of loss and/or advancing age or frailty.

Therapists of older adult patients are often surprised by the emergence of erotic countertransference during more intensive therapy and may recoil from or deny its presence or feel uncomfortable about aspects of the patient's sexual feelings, thereby depriving the therapy of crucial areas of work.

The sometimes-overwhelming effects of cumulative life trauma are painful for therapists, who may retreat into mechanistic or formulaic approaches, inhibiting their own empathetic relatedness.

A young therapist was surprised when a difficult older adult woman complained angrily about feeling manipulated and exposed when sent home to write her life story, a technique the therapist had read was suitable for the older adult. In a discussion of the case with his supervisor, it became evident that he felt overwhelmed by the patient's painful life and uncertain of what would be helpful. Rather than engaging her to understand her feelings, he prematurely employed a cognitive intervention that made her feel infantilized and rejected.

The process of termination may mobilize the very conflicts and issues that led to therapy, such as the loss of a loved one. Nevertheless, the termination process affords another opportunity for the patient to work through conflicts about the finitude of life and relationships, feelings about abandonment and loneliness, and dependency.

In approaching termination, older adult patients need to be assured of the therapist's continued future availability should the stresses associated with advancing age precipitate regression, conflict, and decompensation. While some older adult patients terminate successfully, for many, therapy is an intermittent process to be resumed as needed. The therapist can ease the patient's return to therapy by anticipating, with the patient, reasons that may inhibit reinstating therapy, such as fear of disappointing the therapist and feeling ashamed because symptoms have recurred. Termination is sometimes imposed by unanticipated events, such as illness. Both patient and therapist must deal with the emotional impact. The focus of the relationship shifts from coping with life to dealing with illness and, in the extreme, death.

Older therapists may find that patients who terminated years before successfully return to therapy as they become older. Age-related emotional disruption may emerge superimposed on deeper psychodynamically and developmentally determined vulnerabilities which had been dealt with in younger years. Examples of age-related themes that have precipitated a return to therapy have included forced retirement and loss of purpose and status, fears of age-related physical illness, loss of a spouse through dementia or death, and anxiety or depression often associated with subtle early cognitive decline. Psychotherapists must be technically agile in adapting interventions to the new aging context and capacities of such returning patients, often layering cognitive, behavioral, problem-solving, and interpersonal foci onto their prior understanding of the patient's lifelong internal emotional conflicts.

Contraindications

There are few contraindications to psychotherapy, although the form of treatment is carefully tailored to the needs of the patient. Psychoanalytic psychotherapy is approached with caution. The therapist first ensures that the patient retains sufficient ego capacity to deal with regression during therapy, work through adaptive mourning, and has the capacity to replace lost sources of self-esteem.

As in younger populations, CBT is indicated for the treatment of acute or chronic depressive disorders, concurrent with antidepressant medications when indicated, and for symptoms associated with a personality disorder. Mild cognitive impairment secondary to dementia is not a contraindication to CBT, although suicidal depression or severe cognitive decline requires alternative therapies.

Goals of Treatment

Psychotherapy is most effective when it is used for specific indications with defined goals. Goals are modified to fit the function, cognition, and psychological capacity of each patient. Generally, the greater the frailty, the more modest the goals are. Goals for patients able to undertake dynamic psychotherapy include psychological mastery over the past and its unresolved grief; resolution of adult and childhood sources of shame and guilt; resolution of current interpersonal conflicts, especially with spouse or adult children; working through conflicts associated with loss of self-esteem and establishing substitute sources of gratification for those that had to be relinquished; coming to terms with failure to achieve ideal aspirations; and, at the most advances level, processing and integrating unconscious conflicts experienced in the therapeutic transference relationship. Pollock has termed the creativity and energy that may be released by the successful resolution of losses *mourning-liberation.*

In crisis therapy, the goal is to reestablish the patient's best premorbid level of function. Examples include acceptance of appropriate levels of dependence or controlling excess, psychologically induced morbidity.

For the more debilitated, frail, older adult patients, psychotherapy goals are often symptom-focused behavioral changes. These include focal interventions, for example, dealing with dementia-related behaviors such as aggression, excess withdrawal, agitation, or delusions. With these patients, therapy goals include strengthening the roles of family CGs and fostering a more appropriate, supportive environment for the patient.

ETHICAL ISSUES

Frail, institutionalized older adult patients have limited capacity to use traditional psychotherapies. They are easily viewed by therapists as beyond help. In allocating scarce resources, therapists struggle with whether to expend effort on this population or reserve it for their more vigorous older adult patients. This is a difficult ethical dilemma since frail older adult patients are the most dependent and helplessly reliant on CGs, who in turn are burdened with the role of deciding who shall or shall not receive certain forms of care.

While most forms of psychotherapy require the active participation of patients and, therefore, their inherent consent, behavioral interventions may be applied to the patient externally. In using behavioral techniques with frail older adult patients, therapists are advised to exercise caution in distinguishing between externally imposed goals of therapy, that is, a focal symptom that is troublesome to staff, and the overall welfare of an often helpless patient whose ability to consent to, and participate in, setting treatment goals is limited.

Clinicians are often confronted with ethical concerns over confidentiality and the patient's decision-making capacity. Both family members and therapists may inadvertently infantilize more frail patients and override their right to participate fully in the therapeutic decision-making process. The psychotherapist must carefully evaluate a patient's ability to make decisions. Similarly, the family's right to know about the patient and participate in therapy is carefully balanced by the preeminent right of the competent older adult patient to confidentiality in the therapeutic relationship. In practice, this is often a difficult issue for therapists, especially when families are intrusive, demanding, or litigious.

FUTURE DIRECTIONS

Conclusions about the efficacy of psychotherapy have remained restricted to older adult patients motivated to participate in research who are typically healthy, community-residing Caucasians in their 60s and 70s. While the evidence for the effectiveness of interventions continues to grow and support psychotherapy in various conditions, it is somewhat narrowly focused on CBT, PST, and reminiscence therapies. Given the current understanding that motivation and compliance with psychotherapy are major factors governing success, it would be helpful to understand older adult persons' resistance to therapy and strategies to prevent premature termination.

55.4i Cognitive-Behavioral Therapy

JOHN R. MCQUAID, PH.D., ERIC GRANHOLM, PH.D., AND PATRICIA A. AREÁN, PH.D.

DEFINITION

Considerable progress has been made in developing cognitive-behavioral therapy (CBT) interventions for use in older people with anxiety, depression, and psychotic disorders.

CBT is a form of psychotherapy that attempts to change the interpretations of experiences that determine feelings and behaviors with the goal of reducing symptoms and improving functioning. The premise of CBT is that cognition (the process of acquiring knowledge and forming beliefs) can influence feelings and behaviors. CBT interventions help people to identify and modify thoughts and misinterpretations of experiences that are at the root of problematic behavior. Behavioral interventions (increasing rewarding activities, practicing new skills) both improve mood and provide opportunities to test the accuracy and benefit of beliefs that may contribute to psychological symptoms and impaired functioning.

ADAPTING CBT FOR OLDER CLIENTS

Cognitive therapy is often described as a manualized and structured form of psychotherapy. It is true that there is a strong emphasis on using standardized and validated interventions along with an ongoing assessment of change in targeted symptoms and behaviors. However, when provided optimally, CBT is individualized for the specific client, regardless of age or aging-related issues. Problems and goals are identified in a collaborative manner, activities and skills are designed for the specific needs of the client, and the therapist and client continually review progress to determine whether treatment is providing the desired benefit. Clinicians should keep in mind that treatment modifications should not be made solely on the basis of a client’s age but should be made when issues such as cognitive impairment, disability, and illness are present that can influence the effectiveness of treatment. These issues can occur at any age but are particularly prevalent in older adults and especially common among those who are 75 years old or older. Therefore, before making any major accommodations, a good clinician assesses the need to make them first rather than solely making assumptions about the client’s age.

Ageist Beliefs and Age-Related Challenges

One of the age-specific modifications clinicians may need to consider to do with cohort beliefs about seeking help and ageism. Older adults are less likely to seek help for mental health problems than younger adults and have been noted to hold erroneous beliefs about aging. Cohort-related beliefs can devalue therapy (e.g., “Don’t air your dirty laundry”) and ageist beliefs held by both therapists and clients (e.g., “I’m too old to learn or change”) can interfere with participation in therapy. Just as they can be applied to beliefs that increase psychiatric symptoms, thought-challenging interventions can also be used to modify ageist beliefs that interfere with treatment participation. Similarly, using CBT techniques to address interpersonal and behavioral challenges related to aging is also necessary, such as role-playing age-relevant interpersonal situations (e.g., talking to a doctor about health concerns or eyeglasses) and practicing solving age-specific concerns (e.g., finding transportation, coping with hearing or vision problems).

Transportation Barriers

Transportation and ambulation problems, which are more common among older clients, can further exacerbate problems with isolation and withdrawal from society. It may be necessary to provide transportation to therapy sessions or conduct therapy at convenient locations in the community. Providing treatment in the community can also reduce the stigma associated with going to a mental health clinic, which can especially deter older clients.

Cognitive Impairment

Addressing neurocognitive impairment is another important factor to consider when designing CBT interventions for older adults. Due to normal aging and lifetime comorbid factors that can impact cognition in older clients, especially those with severe mental illnesses (e.g., poor education, lack of work, physical illness, poor nutrition, poverty), cognitive functioning may be impaired to a greater extent in older clients. Simplifying and slowing down discussions, repeated practice of skills, and neurocognitive compensatory aids (e.g., reminder notes, treatment workbooks, writing down information in session, and acronyms to help with skill recall) can be used to help alleviate cognitive impairments. Given fine motor and vision difficulties that are also common in older clients, cognitive compensatory aids and educational materials should use large fonts and writing spaces. Clinicians who have worked with younger populations may need to modify their expectations about the speed at which change may take place, without assuming that older clients cannot make change.

Medical Problems

Many medical impairments increase in frequency as people age. With longer life spans, there is increased exposure to a variety of medical ailments, including cancer, heart disease, musculoskeletal disorders, and other chronic health problems. These changes in health have a number of direct and indirect effects on psychiatric symptoms and treatment. Physical suffering can directly influence mood, anxiety, and psychotic symptoms. In addition, reductions in physical health can interfere with engaging in rewarding activities, demands of health care can reduce financial resources, and sensory impairments secondary to health problems can interfere with both daily activities and interpersonal interactions. All of these problems can also interfere with participation in CBT, which emphasizes the active practice of new skills. Therefore, behavioral interventions need to focus on increasing client activities within the constraints of their medical condition. In addition, cognitive interventions can be beneficial if they help clients to shift perspective from the negative aspects of illness and to focus on thinking that can improve their experience in the moment, even in the context of medical problems.

Role Changes

Aging is associated with transitions through different roles across stages of life. Some of these changes can be disruptive for people, particularly if they are unexpected or involve loss of important sources of reinforcement. For example, retirement may be a positive experience for many, but for some, it can be very disconcerting, particularly individuals who defined their worth primarily through their productivity. Other role transitions involve profound loss, such as changing from a spouse to a widow(er) or divorcee, or from a homeowner to a member of an assisted-living community. In addition, for some individuals role changes include unexpected demands of caregiving at an older age, either of a spouse, child, or grandchild, or alternatively losing independence and needing the aid of a caregiver. These role shifts can involve both changes in self-image as well as physical and emotional demands. These changes can contribute to depression by either reducing access to rewarding activities (e.g., work) or by activating beliefs the client has that can be depressogenic (e.g., “I’m unproductive and useless”). They can exacerbate anxiety symptoms as individuals face uncertainty and increased perceived risk (e.g., “my wife handled the finances, how can I manage without her”?).

When clients are facing such role changes, CBT can be particularly beneficial. On the pragmatic side, behavioral exercises such as scheduling, information gathering, and contacting support resources can help patients more effectively navigate the role change. Cognitive interventions can address depressogenic thoughts, challenge beliefs that are inconsistent with the new role, and generate thoughts that are likely to improve functioning. These efforts can work in service of modifying schema that are less beneficial in the new role (e.g., seeing one’s value as connected to productivity; feeling dependent on others) to a schema that is more functional given the realities of the situation (e.g., seeing one’s self as innately valuable; remembering that new skills can be learned).

Interpersonal Events

Older adults are vulnerable to changes in their relationships that can have important implications for their mood and functioning. Deaths of spouses, other family members, friends, and acquaintances can both provoke grief and represent loss of important social supports. Interpersonal relationships can end through other means as well, including adult children moving away from home or the patient leaving the work environment. In addition, changes in relationships associated with aging, such as having a child become a caregiver of the older person or needing to become a caregiver of an older person, can strain those relationships.

Issues of loss, isolation, and improving social support, leisure activities, and interpersonal communication skills, therefore, are even more important for older clients. Again, the combination of behavioral activities, such as communicating with supports or developing new activities that can increase positive contacts, as well as thought challenging to reduce cognitions that exacerbate the pain associated with interpersonal events can be important themes in CBT for older adults.

Culture and Age Cohorts

Broadly defined, culture provides the context that guides the development of beliefs and expectations. That context changes over time. Among geriatric populations, different age groups have different expectations. The oldest members of society, having lived through the Great Depression and World War II, grew up with different cultural expectations than their children, who were born during and after World War II and came of age during the 1950s and 1960s. It is important for therapists to assess each person’s developmental history with a focus on understanding the beliefs and values that arose from that history. This assessment can then help in developing interventions that address unhelpful thoughts and behaviors while supporting the core values of the client. In addition, the assessment is critical to prevent clinicians from relying on general assumptions about a particular age cohort, but rather to have an understanding of how the experiences shaped the person with whom they are working.

In reviewing the domains above, two major themes arise: *Loss* (of health, role, loved ones, finances) and *danger* of further losses in these domains. Loss tends to be associated with risk for depression and perceived danger with risk for anxiety. Treatment for older individuals in particular needs to address coping with such losses in a constructive manner, helping clients differentiate between likely and unlikely threats, and identifying coping strategies for upcoming risks.

Traditional CBT emphasizes change orientation, attempting to change how one acts and thinks to improve mood. However, emphasizing change alone can be limited in effectiveness and potentially invalidating the client, if the therapist does not also acknowledge the unchangeable nature of some challenges in the older person's life. Some CBT experts refer to this as "the healthy management of reality." From this perspective, the role of CBT is to help clients accurately understand the challenges they face, and then when appropriate modify their actions and thoughts so they can live a meaningful and rewarding life within the context of those challenges. Recent models that have derived from CBT and incorporate acceptance and mindfulness approaches (including dialectical behavior therapy, acceptance and commitment therapy, and mindfulness-based cognitive therapy) all emphasize both skills in change as well as acceptance of unchangeable realities. These treatments tend to incorporate skills for distress tolerance and mindful observation to aid in managing unmodifiable aspects of life experience.

Implications of the COVID-19 Pandemic

Most of these factors have been exacerbated by the COVID-19 pandemic. Older adults have been most vulnerable to this disease, suffering the highest mortality rates. They have experienced disproportionate levels of isolation and loss and increasing psychiatric symptoms. However, the pandemic has also created pressure for adoption of novel approaches to communication and care delivery, particularly the use of telemental health/video conferencing. While this has been broadly adopted and there is research demonstrating CBT is effective via telemental health, some have raised concern over whether older clients can and will use technology such as video conferencing to conduct psychotherapy. While there is limited research in this domain, there is growing evidence that older clients are both willing and able to adopt this technology an dissatisfied with geropsychiatry services in general delivered by telemental health. The authors have had experience of successfully implementing CBT via video in the context of the COVID-19 pandemic with older clients and generally found broad acceptance and appreciation of the benefits of reduced risk and increased access to care. This highlights the need to avoid allowing biases regarding older adults to guide decision making and to engage in collaborative coordination with clients.

TECHNIQUES

Stages of Cognitive-Behavioral Therapy

In general, CBT can be framed in three stages. The first stage is assessment and initial treatment and includes definition of clients' current problems and goals, education about the model of treatment, establishment of a collaborative relationship, and agreement on a treatment plan. In addition, the therapist begins to develop a case formulation. The formulation is a model that attempts to explain the current difficulties in terms of a schema (an organizing set of deeply held beliefs that define the client's perception of self and determine the information that the client attends to, remembers, and recalls, and how that information is interpreted). One goal of this phase is to instill hope that improvement can occur, if possible through the client experiencing some symptom relief secondary to an initial exercise or homework assignment. The middle stage of therapy focuses on skills acquisition, with the primary goal of the client learning to implement CBT interventions independently. The final stage, relapse prevention and termination, emphasizes consolidation of skills, problem-solving obstacles to skill use, identifying potential risks for symptom exacerbation, and developing a plan to apply learned skills in the case of symptom recurrence.

Assessment and Initial Treatment

CBT emphasizes objective measurement of constructs whenever possible, and this begins in the assessment phase. When working with older clients, this will include assessing not only symptom severity, but also the resources available and the challenges faced, and then trying to define all these factors in objective terms. Number of supports, income relative to expenses, health limitations, and caregiver responsibilities are all-important aspects to assess. In addition, standardized measurement of symptoms provides a baseline to assess progress in treatment. In particular, the use of measures with normative data for older populations (such as the Geriatric Depression Scale) is important because several symptoms of depression and anxiety (e.g., sleep changes, reduced energy, memory, and concentration difficulties) can occur in older populations independent of depressive symptoms, and therefore measures need to account for these potential confounds.

As noted above, a key goal of the initial assessment is the development of a case formulation. A case formulation provides a framework for choosing interventions that match the specific needs of the client. Case formulation is particularly important when dealing with special populations such as older adults because it guides both the assessment and the treatment. A well-defined case formulation increases the likelihood that areas such as those reviewed above are addressed and incorporated into treatment.

Juanita was a 69-year-old divorced, unemployed, heterosexual, cisgender Mexican American woman who supported herself on her Social Security benefits. She lived in a one-bedroom apartment. she was serving as guardian of her 5-year-old grandson following his mother’s incarceration. She presented with the following concerns:

1. Depressed mood: Juanita reported daily crying, anhedonia, increased appetite and weight gain, feeling tired “all the time,” feelings of guilt and shame, and thoughts of death.
2. Anxiety symptoms: Juanita met criteria for generalized anxiety disorder. She reported constant excessive daily worry about both major stressors (her daughter’s legal troubles; financial stress) as well as other factors (her children, her friends, safety).
3. Daughter’s arrest and custody of grandson: Her daughter had been arrested approximately 1 year prior to treatment, leading to Juanita receiving custody of her grandson. Her grandson frequently cried at night for his mother, and Juanita felt overwhelmed by trying to provide for his care. Her daughter was incarcerated several hours from where Juanita lived, limiting visitation.
4. Health problems: Juanita had type II diabetes. She had difficulty managing her symptoms in part due to anxiety about checking her glucose levels. Juanita met criteria for obesity and worried that her diabetes would progress and lead to amputation of her foot.
5. Social isolation: Although Juanita had family and friends in the area, she rarely contacted them or answered her phone.

In the intake interview, Juanita stated, “I tried to be a good mother, but I failed. And now I’m going to fail my grandson.” When discussing goals, Juanita stated that her greatest concern was her daughter’s and grandson’s futures. In discussing this goal in terms of what Juanita could influence, she agreed that she would like to provide a safe and loving environment for her grandson and to be a support for her daughter. These goals required her to take several actions around caring for herself, including:

1. Reconnect with family and friends to increase pleasant activities and get help with caring for her grandson
2. Improve her diabetes care and reduce weight so that she could be physically better able to care for her grandson
3. Generate additional income by re-establishing her home-based business sewing traditional dance dresses for a local dance studio
4. Make arrangements to visit her daughter in prison with her grandson on a regular schedule

In this case, several of the described factors that are associated with depression and anxiety in older people were apparent. Juanita had clear medical problems that limited her activities, she had limited resources, and she was isolated from support (albeit by her own actions). She also experienced a clear loss (her daughter being incarcerated) and a demanding role change (becoming caregiver to her grandson). In the context of the meaning she ascribed to these events ("I failed"), it is not surprising for her to be experiencing depressive symptoms. Of particular note, her anxiety and depressive symptoms were exacerbating both her health problems (interfering with diabetes management) and interpersonal functioning (avoiding supports).

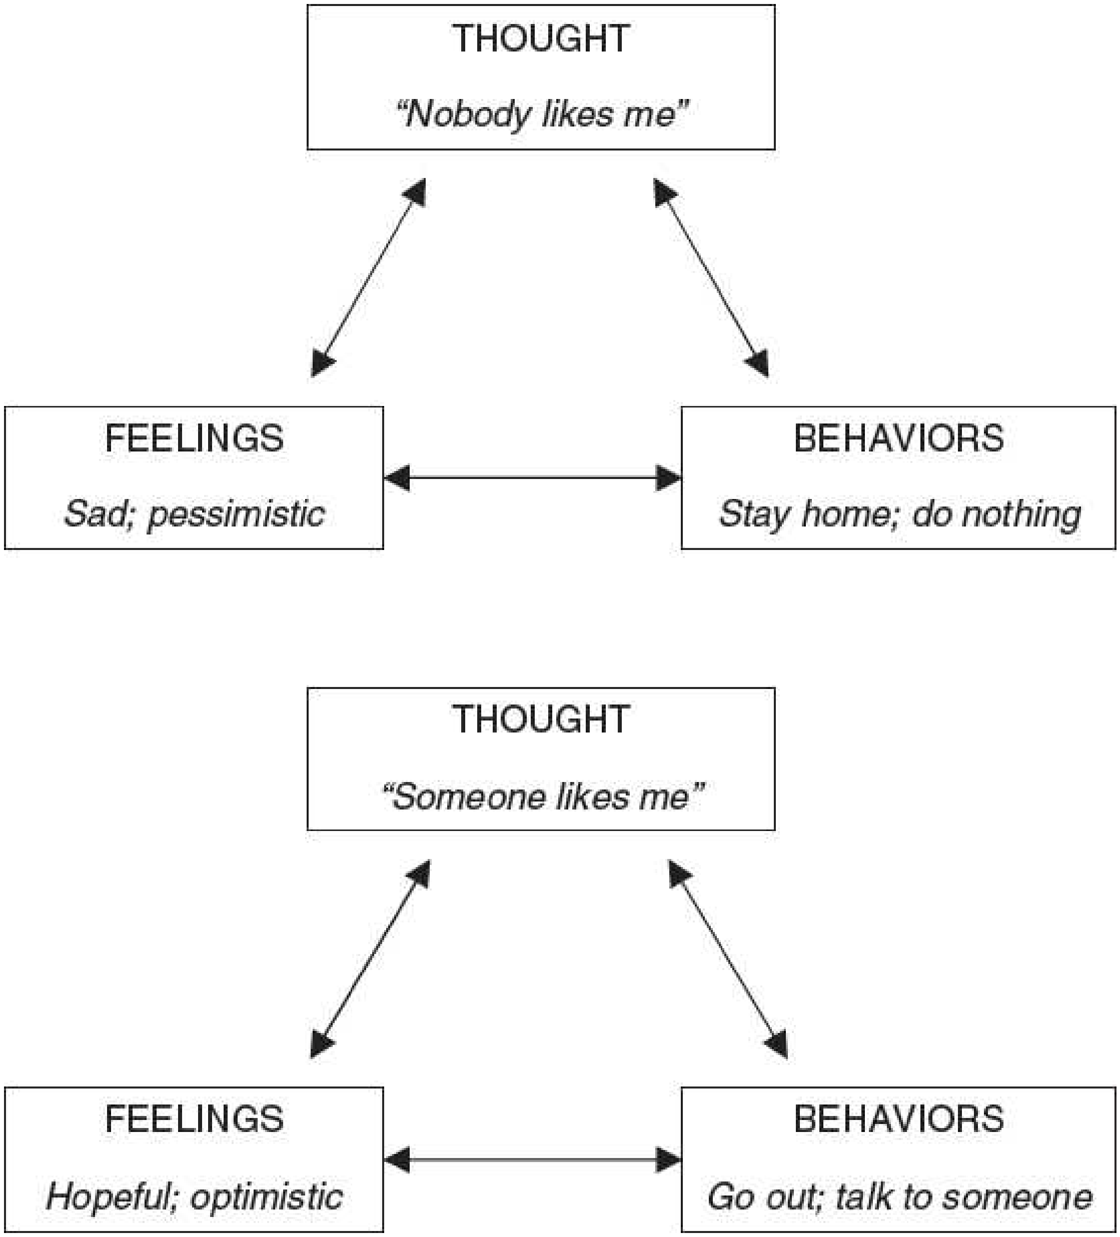
In reviewing the goals, the initial theme expressed by Juanita was a desire to care for others. However, the therapist was concerned that without taking care of Juanita's own issues, she would be unable to achieve her goals. Therefore, the therapist helped focus on self-care in terms of necessary preparation for her goal of caring for others. In this case, the proposed formulation identified a potential core belief held by Juanita of "I am undeserving; I need to care for others to get love." Rather than directly challenging this initially, the therapist first worked with strategies to achieve the goals Juanita had identified. Over the course of therapy, an additional goal of schema change (moving from "I'm undeserving and need to care for others to get love" to "I am a good and deserving person who loves to care for others") was instituted, but initially therapy focused on engaging Juanita in treatment so that she could gain some symptom improvement before taking on the more difficult tasks of acceptance and schema change.

In working with the therapist, these general goals of providing for her grandson were translated into more specific actions that could meet her goals and be beneficial to her in terms of improving her mood and functioning.

Middle Stage Interventions

Although the interventions in this stage of therapy are generally divided into behavioral and cognitive interventions, such interventions frequently have both cognitive and behavioral aspects. Behavioral interventions can lead to changes in cognition (e.g., doing an activity and finding out it is more enjoyable than predicted), while cognitive interventions can be useful in helping patients to do behavioral interventions (e.g., challenging the belief that one has to "feel" like doing something before doing it). Research has shown that conducting either cognitive or behavioral exercises leads to change in both cognition and behavior. In general, interventions focus initially on assessing baseline thoughts and activities and their relationship to mood and other outcomes. Clients then learn change strategies and coping skills in this stage of therapy and assess whether these skills are effective in improving outcomes.

Psychoeducation. This initial assessment of thoughts and activities and their relationship to mood and other outcomes provides an opportunity to introduce the cognitive model and the idea that thoughts influence feelings and behaviors. The groundwork for future cognitive work is laid by using the client's own experience to illustrate how thoughts relate to moods and behaviors. With all clients, but particularly with older clients with cognitive impairments, it is helpful to draw on a pad or marker board or use a handout to illustrate associations between thoughts, feelings, and behaviors, as shown in Figure 55.4i–1.



THOUGHT
"Nobody likes me"
FEELINGS
Sad; pessimistic
BEHAVIORS
Stay home; do nothing
THOUGHT
"Someone likes me"
FEELINGS
Hopeful; optimistic
BEHAVIORS
Go out; talk to someone

FIGURE 55.4i–1. Generic cognitive model illustrating relationships between unhelpful (**top**) and helpful (**bottom**) thoughts, feelings, and behaviors.

Depending on individual client needs, it may also be important to provide education about symptoms associated with specific diagnoses, the action of medications, medication adherence strategies (especially in the context of memory impairments), and complementary interactions between medication and psychotherapy treatments. It is often useful in this context to provide education about the vulnerability-stress-coping model of mental illness, focusing on the interaction of biologic vulnerabilities, stress triggers, and coping strengths in symptom exacerbation or relapse. Finally, it is generally best practice in all mental health interventions to provide education about triggers and signs of crisis, assess risk for suicide, and develop an individualized safety plan for prevention of suicide or relapse/hospitalization as indicated.

Behavioral Interventions. Behavioral interventions in CBT for mood disorders tend to emphasize activities that increase positive affect, gather evidence to challenge unhelpful beliefs or both. Initial interventions can solely consist of *activity tracking* (e.g., recording a baseline of all activities that a person is doing throughout the day). Activity tracking helps clients recognize their current activity level, potentially challenge unhelpful beliefs like "I never do anything" and identify opportunities for further intervention. *Activity scheduling* is simply identifying one or more activities that clients may find rewarding and planning them into their day. Keys to successful activity scheduling are generating multiple options, working with the clients to identify choices they believe they can complete, and problem-solving potential obstacles to the activity. In addition, tracking relevant emotions (e.g., depression, anxiety, happiness) before and after the activity can help clients notice whether there is any benefit. In older adults, medical problems can significantly limit mobility and activity, and some beliefs (e.g., "But, I've been doing it this way for years") can make changing routines particularly challenging. However, activities do not have to involve strenuous physical activity to enhance mood or alter cognitions, and most clients can manage some change in routine if care is taken to address interfering cognitions and problem-solve around limitations.

A variant of activity scheduling is *pleasure predicting*. This is a useful technique when clients doubt that they will enjoy an activity. In addition to rating mood before and after the exercise, clients are asked before they do the activity to predict how much they will enjoy it and then rate the actual enjoyment once completed. Comparing the predicted outcome with the actual outcome helps challenge the belief “I won’t enjoy it” and helps to highlight the tendency to underestimate the benefit of pleasant events.

For anxiety disorders, behavioral interventions include graduated exposure, which involves engaging in feared activities in an organized fashion. Using principles of systematic desensitization, clients break down a feared activity (e.g., shopping in a store) into specific steps that are arranged from least anxiety-provoking to most (e.g., shopping in a large grocery store early when no one else is there versus shopping in a small crowded shop at the busiest time of the day). Clients practice doing less anxiety-provoking tasks first and then move on to the next task. Clients may become less physiologically reactive to the feared situation, as well as develop more helpful cognitions (e.g., “I can handle this.”) although research indicates that the violation of the expectation of a negative outcome is key to overall improvement, even if anxiety in the specific exposure does not decrease.

Clients in anxiety treatment can also be taught a variety of relaxation techniques, such as progressive muscle relaxation or breathing retraining, to facilitate management of their anxiety symptoms. The limited research available suggests that relaxation alone can be as effective as CBT for reducing anxiety symptoms in older clients. Recommendations specific to late-life anxiety include (1) ensuring that sufficient time is devoted to learning relaxation training skills, (2) emphasizing in vivo rather than imaginal exposure exercises, and (3) de-emphasizing more abstract cognitive restructuring techniques (e.g., directly disputing dysfunctional thoughts).

A related exercise that has been incorporated into both anxiety and depression treatment, and to some extent acceptance interventions for psychosis, is mindfulness meditation. Mindfulness is defined as paying attention in a purposeful way, in the moment, nonjudgmentally. Clients are taught to allocate their attention to a particular stimulus (e.g., their breath), and to just notice this. As distractions arise (e.g., internal thoughts, external sounds), clients learn to just notice these, as well as their own reaction to them. They then return attention to the target stimulus. Mindfulness is a particularly useful skill in depression and anxiety for helping clients learn to observe their thoughts. When people notice their thoughts, they can then question the accuracy of them and do not need to act on those thoughts.

Juanita had stopped communicating with other family members, even though this had been a rewarding activity in the past. Therefore, therapy focused on this as an opportunity for behavioral activation.

Therapist: One thing you told me is that you used to enjoy time with your son and his family. Why don't we work on arranging some time with them?
J: Okay.
T: Okay, so what day and time do you think makes sense?
J: Well, my son works, so it would be best on the weekend, maybe in the afternoon.
T: How do you usually arrange to get together?
J: I just call him up and tell him I'm coming over.
T: Is there anything stopping you now?
J: I just don't want to be around people. I just feel like I'll bring everyone down. That would just make things worse.
T: Remember, part of the goal is to test beliefs like that. Would you be willing to go visit and then write down your evidence as to whether you brought everyone down and things got worse?
J: Okay.

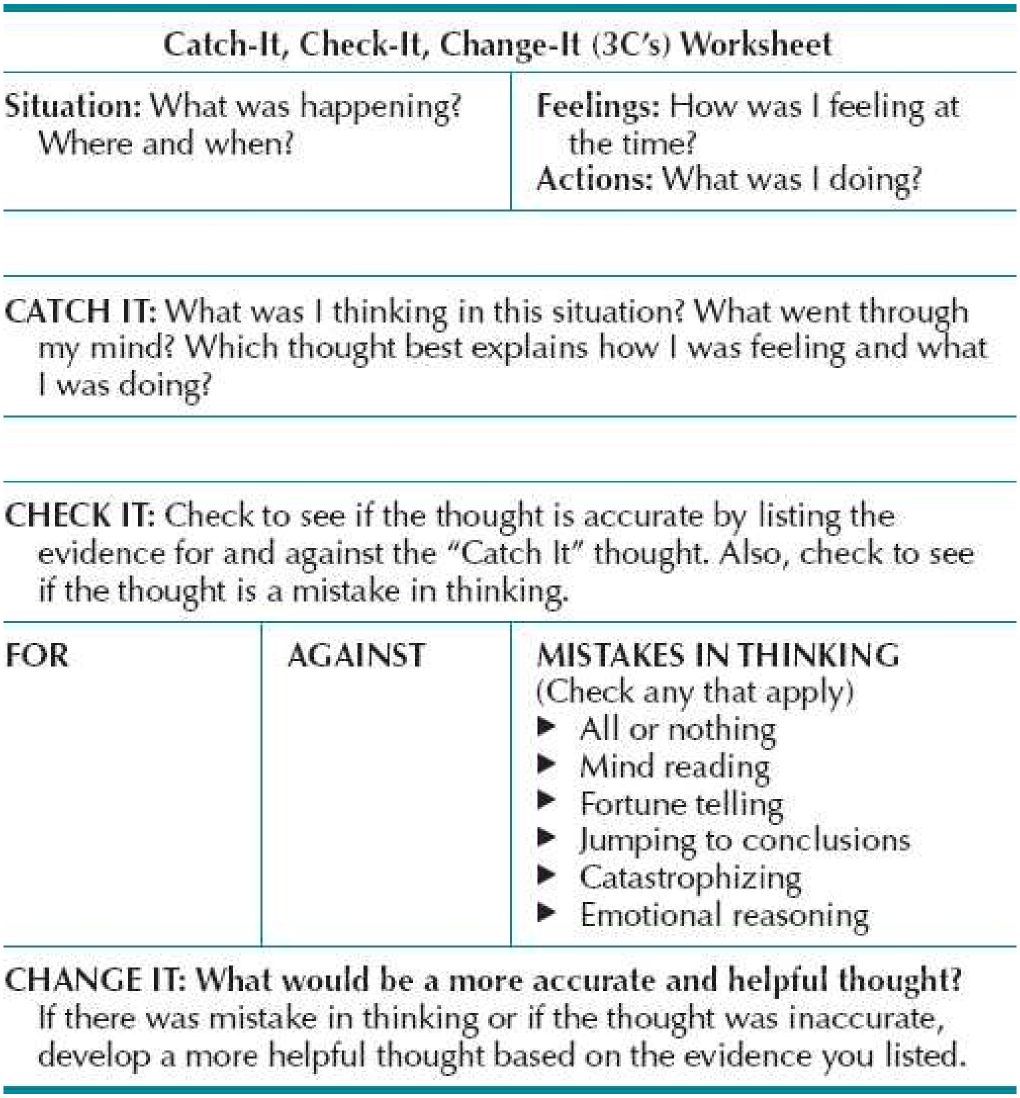
This example highlights several important skills: Activity planning (spending time with the family), identifying obstacles (thoughts about her response), and challenging thoughts (gathering evidence from the experience).

Cognitive Interventions. One of the key skills that clients learn is thought challenging. The key steps to thought challenging are:

1. Noticing clients’ thoughts and identifying their effect on mood and behavior
2. Learning to test the helpfulness and/or accuracy of those thoughts
3. Generating a new, more accurate, or useful thought
4. Examining the effect of the new thought on mood and behavior to determine if it is an improvement

For some clients, the initial task of noticing thoughts is challenging. For clients who have difficulty even noticing their thoughts, a form such as the automatic thoughts checklist can be helpful. This is a list of thoughts associated with depression. Clients read through the list and check those that they experience. Once clients can recognize their thoughts, there are a variety of forms for teaching clients to examine and change them. With older clients, a straightforward model, such as the “3C’s” form, can be useful because it is a simple model (Table 55.4i–1). Clients are initially taught to write down thoughts in the “catch it” column and the relationship to their mood in the “check it” column, as well as any errors or problems with the thought. Once clients can recognize their cognitions, they learn strategies to question and challenge thoughts that are unhelpful and write down more helpful thoughts in the “change it” column. Strategies include identifying common unhelpful thoughts (e.g., all-or-nothing thinking, predicting the future) and examining evidence both in support of the unhelpful thought and in contradiction to it. Throughout these exercises, clients are taught to determine the effectiveness of these efforts by rating changes in their mood in response to the new thought (Table 55.4i–2).

Table 55.4i–1.
3C's Homework Form



<table>
<tr><th colspan="3">Catch-It, Check-It, Change-It (3C's) Worksheet</th></tr>
<tr><td colspan="2">Situation: What was happening? Where and when?</td><td>Feelings: How was I feeling at the time?
Actions: What was I doing?</td></tr>
<tr><td colspan="2"></td><td></td></tr>
<tr><td colspan="3">CATCH IT: What was I thinking in this situation? What went through my mind? Which thought best explains how I was feeling and what I was doing?</td></tr>
<tr><td colspan="3"></td></tr>
<tr><td colspan="3">CHECK IT: Check to see if the thought is accurate by listing the evidence for and against the "Catch It" thought. Also, check to see if the thought is a mistake in thinking.</td></tr>
<tr><td>FOR</td><td>AGAINST</td><td>MISTAKES IN THINKING
(Check any that apply)
▶ All or nothing
▶ Mind reading
▶ Fortune telling
▶ Jumping to conclusions
▶ Catastrophizing
▶ Emotional reasoning</td></tr>
<tr><td colspan="3">CHANGE IT: What would be a more accurate and helpful thought? If there was mistake in thinking or if the thought was inaccurate, develop a more helpful thought based on the evidence you listed.</td></tr>
</table>

Table 55.4i–2.
Common Types of Unhelpful Thinking

All or nothing	Viewing situations in terms of absolutes: “I am a complete failure”
Selective attention	Attending to negative information and/or ignoring positive information (e.g., noticing health problems and ignoring supportive family members)
Shoulds	Holding rigid rules and expectations; refusing to accept realities outside one’s control: “I should be able to do all the things I used to do.”
Emotional reasoning	Judging a situation based on one’s emotional response, rather than objective evidence: “I was feeling anxious; therefore, I must have looked foolish.”
Mind reading	Making assumptions about others’ perceptions: “They think I’m too old.”
Predicting the future/probability estimation errors	Overestimating the likelihood of a negative event: “I know that I will fall and break my hip if I go to the store.”
Catastrophizing	Underestimating one’s ability to cope with a negative event: “I can’t stand it if I get sick.”
Over-responsibility	Feeling guilt for situations outside of one’s control: “It is my fault my grandchildren are unhappy.”

Many people, including therapists and older people themselves, hold unhelpful beliefs about older adults. These can include thoughts such as, “Older people can’t learn/change,” “Others do not want to be around older people,” “Older people are a burden,” or “Older people don’t have much to give.” Beliefs about managing suffering (“Don’t air your dirty laundry”) or about therapy (“Therapy is for crazy people”) can also interfere with the acceptability of treatment. Therapists need to attend to both of these sets of beliefs, both in how therapy is initially presented and in the course of the actual treatment.

Mike was a 75-year-old retired, gay-identified cisgender White male whose long-time partner and husband had died approximately 2 years before initiating treatment. He was referred for care by a close friend who was concerned that he was still grieving the death of his husband and had become isolated.

Mike had grown up in a traditional Christian family on a farm in a small Midwest town, the middle of three siblings (an older brother and a younger sister). He reports having a loving mother and distant father, but that he disconnected from his parents and siblings when he started to identify as gay because he anticipated they would reject him based on their religious beliefs. He joined the Navy in part to "escape" small town life. Mike had served as a Navy corpsman including deployment on an aircraft carrier during the Vietnam War. He had no direct combat exposure but was involved in caring for wounded evacuated to the ship.

Mike found his role rewarding and served in the military for approximately 15 years. However, he ended up leaving the military prior to retirement, for which he would have been eligible after 20 years, because rumors of his sexual orientation were beginning to spread among his unit. Upon leaving the military he attended a state university in a large city and obtained his bachelor's degree and teaching credential. He then pursued a successful career as a middle school teacher.

Mike had very limited dating or sexual experience prior to or during his military service, fearing consequences for his career. However, while in school he was active in the gay community of his city, dating frequently. He also reports drinking heavily at this time. He met his partner, Bill, and reports that within a year they had developed a committed relationship. Bill was approximately 10 years older than Mike, and Mike describes him as a partner as well as a mentor helping him navigate the "gay scene." Over the next 10 years with Bill's support, he was able to disclose his sexual orientation to his parents and siblings, and his brother and sister in particular were supportive and developed a close bond.

His parents were initially “disappointed” but eventually “came around.”

Mike reported that his relationship with Bill was marred by several periods of heavy drinking during which Mike had anonymous sexual encounters with other men. When Bill found out about these incidents, they had a series of arguments and confrontations that led to Mike attending Alcoholics Anonymous (AA). They maintained their relationship and married when gay marriage was legalized, and Mike remained sober for the following 30 years. However, Bill would frequently remind Mike of his infidelities and criticize him during times of conflict.

Approximately 10 years prior to Mike initiating CBT, Bill had developed a neurodegenerative disease that quickly limited his physical functioning, and left him bedridden for the last 4 years of his life. Mike served as his primary caretaker throughout his decline, retiring from his job as a teacher to take care of Bill. During this time, as Bill developed symptoms of dementia, he would continue to recall Mike’s earlier infidelities and remind him of how he had hurt Bill in the past.

When initially presenting for treatment, Mike shared that since Bill had died he continued to feel both extreme sadness at the loss and guilt about his previous behavior. However, he also reported anger at Bill’s inability to forgive him, which in turn led to additional guilt. He also reported having “no purpose” now that Bill had passed. Although he and Bill had a large network of friends, he was not interacting with them. While he was still attending AA, he no longer took leadership roles in the organization, sponsored other members, or participated in social events. He only spoke to his brother and sister when they called and had started screening their calls to avoid them.

At the beginning of therapy, Mike was meeting criteria for major depression, including daily sad mood, anhedonia, decreased energy, pervasive guilt, poor appetite, insomnia, and thoughts of death (he denied suicidal ideation, plan, or intent, but thought that the world would be better off without him). He stated he was irritable at AA meetings and took benign comments as criticisms directed at him. He also reported he had not cleared out any of Bill's belongings, and that he criticized himself for this as well.

Therapy focused on three areas: Acknowledging the loss of Bill, developing goals for Mike that were consistent with his values, and increasing his engagement with people who cared about him. Based on his history, the therapist developed a case formulation that focused on the core belief "I'm defective." This manifest in secondary assumptions of "I deserve to be punished" and "I can never be forgiven for the harm I've done." This in turn led him both to be very self-critical and to interpret those around him as being critical as well.

In the course of therapy, Mike learned to examine his thoughts and the relationship between thoughts, actions, and feelings. As an example, he stated that one of his goals was to start cleaning up his home, including donating most of Bill's clothes to charity. However, in the session, Mike reported that he had been unable to donate the clothes and got upset when he thought about it. The therapist helped Mike to examine his thoughts using the 3C's form: In reviewing the thoughts, Mike was guided in identifying thinking errors, in this case, "should" thoughts. He was then guided through questioning the assumptions underlying the thoughts to generate alternative, more helpful thoughts:

Therapist: What do you tell yourself when you looked at Bill's clothes?

Mike: If I get rid of them, I'm being unfaithful. I'm betraying him.

T: When you say that, what emotions come up?

M: Shame, guilt . . . and some anger

T: I can see where the shame and guilt come from; how does that thought lead to anger?

M: I get angry at myself for even wanting to give away his clothes. I shouldn't want to.

T: I see. You're telling yourself there's something wrong with you if you want to give his clothes away; "I shouldn't want to do this." So what would be a more helpful thing to say to yourself?

M: I don't know.

T: Well, what is the reason you want to give away the clothes? Is it because you didn’t love Bill?

M: No! It’s just that it is so hard to see those reminders. I think it would help me move forward.

T: Do you think that Bill would not want you to move on?

M: No, he told me that he wanted me to be happy after he was gone, or at least he did when he wasn’t upset with me.

T: So it sounds like the “should” thought is not true; there are good reasons for wanting to give the clothes away, and it makes sense to want to do so. What would be a more helpful thing to say?

M: Maybe that it’s ok to give the clothes away; it is doing something for others, and Bill would like that.

T: And what’s your evidence that this is true?

M: Well, he told me to move on when he was gone, and he did like donating stuff to charity.

T: Anything else? If the roles were reversed, what would you want Bill to do, if you were gone and your stuff caused him pain?

M: Oh, I’d want him to donate it. I wouldn’t want him to hold onto it.

T: So what might be a more useful thing to tell yourself?

M: He’d be ok with me giving his stuff away because it would be helping others

T: On a scale of 0 to 100, how much do you believe that’s true?

M: I would say about an 80; we had talked about this.

T: When you say that to yourself, what happens to your emotions?

Mike: They get better.

In this example, the therapist asked questions to guide Mike in questioning his assumptions, and to notice evidence that alternative thoughts may be true. The therapist then helped Mike formulate a more helpful thought and tested its usefulness by asking how it affected his feelings, using the 3C’s form.

Situation	Catch it	Check it	Change it
Deciding on what to do with Bill's things	"If I get rid of his clothes, I'm betraying him." "I shouldn't want to give his things away."	Emotions: Shame (90) Guilt (90) Anger (60) Thinking error: "Should" thought	"Giving away Bill's clothes would be helping others, and he'd like that." Emotions: Shame (20), Guilt (20), Anger (30)

Socratic Questioning and Techniques for Getting at Thoughts. Also called "guided discovery," the overall purpose of Socratic questioning is to challenge the accuracy and completeness of thinking. These are open-ended questions phrased, so people rarely respond with a "yes" or "no." It is important that the tone of the discussion remains collaborative and the therapist does not betray their judgment of the client's interpretations. Socratic questioning may be used at almost any stage of therapy and may be particularly useful when resistance is detected. There are several different categories of Socratic questioning, defined below with examples:

CONCEPTUAL CLARIFICATION QUESTIONS. These are basic "tell me more" questions that encourage deeper thinking:

- *What exactly does this mean?*
- *How does this relate to what we have been talking about?*
- *What is the nature of . . . ?*
- *What do we already know about this?*
- *Can you give me an example?*
- *Are you saying . . . or . . . ?*

PROBING ASSUMPTIONS. These are directed at uncovering assumptions underlying beliefs. This can be particularly helpful for identifying underlying core schema.

- *What would it mean about you if . . . ?*
- *You seem to be assuming . . . ?*
- *How did you choose those assumptions?*
- *Please explain why/how . . . ?*
- *How can you verify or disprove that assumption?*
- *What would happen if . . . ?*
- *Do you agree or disagree with . . . ?*

PROBING RATIONALE, REASONS, AND EVIDENCE. These uncover reasoning in arguments.

- *Why is that happening?*
- *How do you know this?*
- *Why do you think X causes Y . . . ?*
- *Are these reasons good enough?*
- *Would it stand up in court?*
- *How might it be refuted?*
- *What evidence is there to support what you are saying (or an alternative)?*
- *When did you first decide this was happening?*

QUESTIONING VIEWPOINTS AND PERSPECTIVES. Most arguments are given from a particular position. Show that there are other, equally valid viewpoints.

- *Another way of looking at this is . . . ; does this seem reasonable?*
- *What is an alternative way of looking at this?*
- *What is the difference between . . . and . . . ?*
- *Why is it better than . . . ?*
- *What are the strengths and weaknesses of . . . ?*
- *How are . . . and . . . similar/different?*
- *What if you compared . . . and . . . ?*
- *How could you look at this another way?*

PROBING IMPLICATIONS AND CONSEQUENCES. The argument given may have logical implications that can be forecasted. Do these make sense? Are they desirable?

- *Is . . . a helpful thought? Is . . . helping you reach your goal?*
- *How does this thought affect how you feel or what you do?*
- *Then what would happen?*
- *What are the consequences of that assumption?*
- *What are the implications of . . . ?*
- *How does . . . affect . . . ?*
- *Why is . . . important?*

Mindfulness and Acceptance-Based Interventions. These interventions can be particularly helpful in helping clients to observe their thoughts and emotions, and to also tolerate distressing situations. Key exercises include body scans (where the client learns to notice each part of the body in order, in a nonjudgmental way) and breath-focused meditation (paying attention to breathing without trying to change it). Clients then learn to use the skills of nonjudgmental observation practiced in these exercises in attending to experiences in their everyday lives.

Schema Change. CBT also addresses schema, defined as core beliefs and associated cognitive biases that are held by people. Common core beliefs in mood disorders focus on achievement ("I am worthless unless I am productive") or affiliation ("I am unlovable"), while in anxiety disorders they focus on vulnerability ("I can't cope; I am insufficient"). Due to the stigma and multiple failure experiences associated with severe mental illness, people with schizophrenia may have both types of core beliefs. In paranoia, core beliefs may also focus on persecution as an explanation for failure ("poor me") or as a deserved punishment ("bad me"). Schema change involves the other treatment techniques previously defined. In addition, the hypothesized schema is generally reviewed with the client, although how this is done and timed is in itself guided by the formulation. For example, someone who has a core belief of "I am incompetent" and a secondary assumption of “I can’t let others see who I really am” may find discussion of a core belief very disrupting early in therapy, whereas someone with the same core belief but a secondary assumption of “others need to help me because I can’t help myself” may find an early discussion positive and supportive. The costs and benefits of the schema are discussed in the context of the current problems and goals, and an alternative schema is derived that is more functional for clients while still being consistent with their values.

Mike frequently expressed the thought “I’m a screw-up; I’m not good enough.” His therapist noted that Mike seemed to believe that there was something inherently flawed or defective about himself and he deserved to be punished. Mike agreed with this. He noted that intellectually, he knew he was trying to be a good person, but emotionally he always felt there was something innately “broken” about him. Through the use of guided discovery, Mike tied this sense of himself as flawed to struggling with his sexual orientation as a young man and the teachings of the church in which he was raised, as well as his infidelities with Bill and Bill’s lasting anger about them. The therapist suggested to Mike that he consider another perspective; what would the people in his life say they valued most about him—Would they focus on his flaws or his gifts? Mike was able to share that his family and friends had all said how much they respected the love and dedication with which he cared for Bill. He also still received cards from former students sharing how important he had been to them as a teacher. In addition, although Bill frequently criticized him, Bill also was very loving and appreciative. In fact, most of the time, they were very loving toward each other, and Mike realized he tended to focus on the negative times. Finally, Mike and his therapist reflected on the strength and commitment it took to have stayed sober for 30 years, and the support he had provided to others in AA, particularly younger gay men struggling with their own sexual orientation.

Mike was willing to consider a more helpful view of himself, and came up with an alternative self-statement; “I am a caring guy.” He developed some new secondary assumptions; “I’ve done things that I’m ashamed of, but I have worked hard to acknowledge my mistakes and make amends” and “I’ve been a good influence in a lot of lives.”

While Mike agreed that these statements were true, he stated “they don’t feel true.” This is a common experience for clients when they generate more accurate thoughts that are in contradiction to long-held schema. Therefore, assignments were designed where Mike would act as if the new formulation was true, and see how it worked for him. This included increasing his contacts with family members and friends, and behaving like he deserved to be happy (e.g., doing enjoyable things). He found contacting people hard initially, but he was greeted with enthusiasm. As he started joining friends for activities, his mood started to improve and he found it easier to act on tasks around the house. He still missed Bill, but now had more support to cope and friends who expressed understanding about his loss.

Termination and Relapse Prevention. As clients achieve symptom improvement and functional gains, the emphasis of CBT shifts to preparing for termination. Treatment emphasizes clients developing their own interventions and experiencing mastery of skills. In addition, the therapist helps the client identify both persistent problems that need to be managed as well as potential future problems, and then identify the skills that can be used to address those problems. Particularly for older clients, termination can be stressful if they have lost other relationships recently. Therapists need to emphasize the goal of the client developing skills, and the importance of independent practice to adequately learn the skills. However, it can also be helpful to schedule follow-up “booster” sessions. This both provides the client with some sense of support and allows a chance to problem solve difficulties in implementation of relapse prevention plans.

Modifications for Psychosis

Psychosis is the most expensive mental disorder to treat, with hospitalization costs accounting for the majority of expenditures. The cost of care for psychosis patients over 65 years old is even higher than for patients aged 30 to 64. Best practice guidelines and nationalized healthcare systems recommend or mandate that CBT be delivered to consumers with schizophrenia as part of a comprehensive treatment program that includes pharmacotherapy and support resources. For example, CBT is among the recommendations made by the American Psychiatric Association, Department of Veterans Affairs, and the Schizophrenia Patient Outcomes Research Team (PORT), a project sponsored by the National Institute of Mental Health to develop evidence-based treatment guidelines for schizophrenia in the United States. PORT client survey findings, however, indicate poor conformance with this recommendation, especially for older people with psychotic disorders. Providers with expertise in delivering these interventions for older people with psychosis are very much needed.

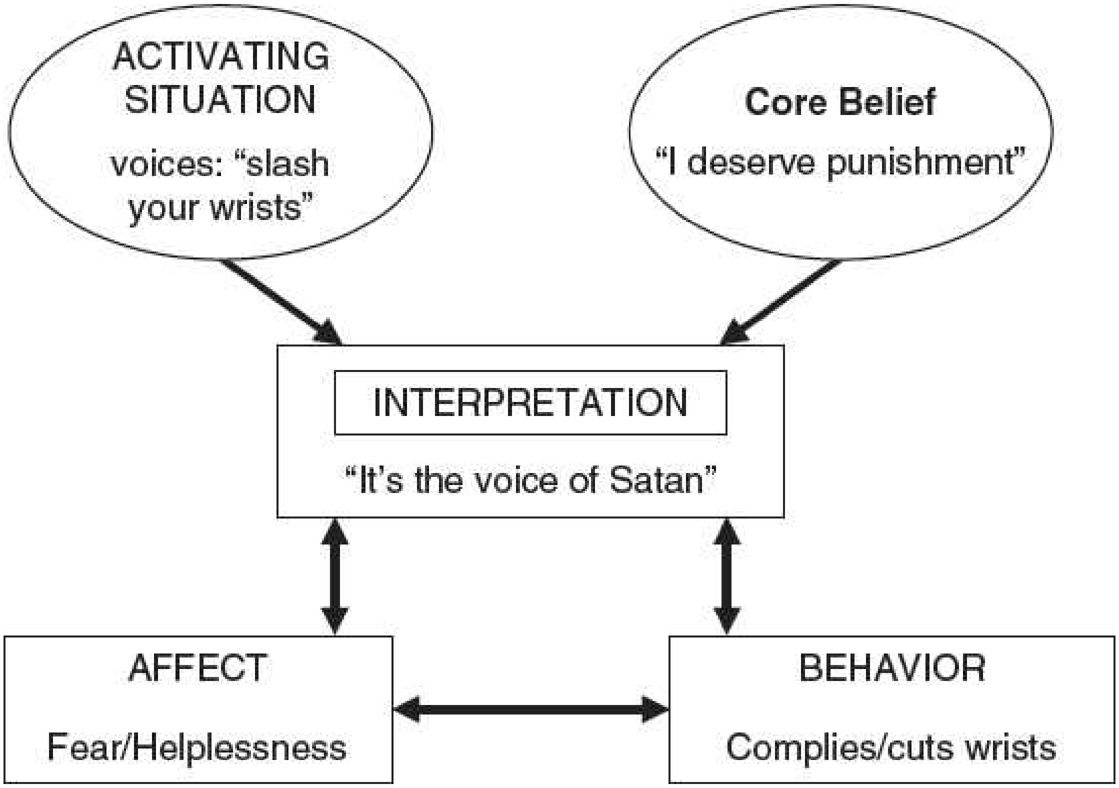
In principle, all of the stages and techniques of CBT discussed above can be applied to the treatment of older people with psychosis, with some modifications but not fundamental differences. All of the techniques discussed above are appropriate for the treatment of the multiple problems faced by consumers with psychotic disorders. In this section, a brief discussion of the vulnerability-stress model and the general cognitive model of schizophrenia is provided, followed by descriptions of specific CBT interventions applied to psychosis, negative symptoms, and poor functioning in older people with schizophrenia.

Cognitive Model of Schizophrenia. In the context of the vulnerability-stress-coping model of schizophrenia, personal enduring vulnerability traits, like cognitive and neurobiologic dysfunction, interact with environmental stressors and coping responses to contribute to symptom formation. Neurocognitive deficits exacerbated by stress hyper-reactivity can lead to decompensation and the emergence of delusional beliefs and hallucinations, as well as diminished capacity to accurately evaluate beliefs. People with psychosis, like healthy individuals, have great difficulty distancing themselves from their highly charged beliefs but also have the added problem of insufficient cognitive resources available to evaluate and correct them. Rigid thinking, perseveration, cognitive biases, impaired abstract reasoning and memory, and cognitive distortions can play an important role in the development of delusional beliefs by leading to exaggerated appraisals of negative life events that become highly charged delusional belief systems.

In addition, multiple failure experiences due to cognitive deficits, odd behavior, and social withdrawal can lead to dysfunctional performance beliefs and social aversion attitudes (e.g., “I am inferior,” “Why bother; I will fail,” “If you can’t do something well, why do it at all”? and “People are against me”), which can exacerbate maladaptive behaviors, such as social withdrawal and suspicious avoidance. In the context of generic cognitive model applied to schizophrenia, dysfunctional attitudes like these may contribute to negative symptoms and poor functioning. Negative appraisals about one’s self and one’s ability to perform goal-directed tasks contribute to passivity and avoidance of productive activities, as a defense against anticipated failure and negative evaluations by others. This avoidance and lack of effort manifest as diminished motivation (avolition-apathy), loss of pleasure (anhedonia-asociality), impoverished speech (alogia), and blunted affect. CBT can be used to address and challenge beliefs about psychotic symptoms, social aversion attitudes, and defeatist performance beliefs, including expectancies (“It won’t be fun”), self-efficacy beliefs (“I always fail”), and anomalous beliefs (“Spirits will harm me”) that interfere with functioning. In addition, by including behavioral interventions, such as social skills training, skills deficits that interfere with social functioning can be addressed. By challenging self-defeating beliefs that interfere with skill performance while addressing skill capacity, people are more likely to engage in functional behaviors and use the skills they have.

Psychoeducation for Psychosis. Education is a key component in helping clients with psychotic symptoms make sense of their experiences. Psychoeducation is best accomplished as a two-way process, whereby the clients themselves come up with psychological explanations of their symptoms using guided discovery with inclusion of information from the therapist only where necessary. It is typically helpful to review the history and symptoms at the onset of psychotic illness in the context of the initial stressors that may have triggered it, using reflections like, “So, with all these stressors going on, including your father’s death, you suddenly began hearing this voice, and tried to make sense of it." Further, "Given that it seemed that nothing else could explain where this voice was coming from, I can see why you decided it was your father talking." Comments like this emphasize both that data were gathered that led to a conclusion about the source of the voice (an empirical approach) and that there were life events that contributed to the experience. This can set the stage for gathering evidence that might dispute these long-held conclusions, as well as identifying potential relapse triggers for relapse prevention plans. It can be challenging to review the first episode in older clients when the first episode was often decades prior. Collateral informants and record reviews can be helpful here, but the most important information is the evidence and context recalled by the client. In older clients, reviewing the impact of recent losses and bereavement (and sometimes anticipated losses or illness of loved ones) on symptom exacerbation can be useful to illustrate the impact of stress on symptoms. In the context of the vulnerability-stress model, it is often useful to focus on "normalization," which involves presenting the idea that any individual is vulnerable to experiencing psychotic symptoms if exposed to certain circumstances and sufficient stresses (e.g., sleep deprivation, unusual severe stressors, or substance abuse). This "normalization" discussion can serve to reduce stigma associated with severe mental illness. The focus on normalization and open questions and reflections directed at an honest understanding of how the client arrived at delusional beliefs often facilitates rapport and builds a trusting relationship. Time and patience are needed in this process, as trust can be slow to develop with some clients (e.g., with paranoia).

Clients are introduced to the general concepts of CBT, including the relationship between thoughts, behaviors, and feelings (cognitive model). Multimedia presentation of information can help compensate for neurocognitive impairment associated with both psychotic illness and aging. For example, drawing figures, like the one below, on a pad (or handout) for clients to take home can help compensate for cognitive impairment (Fig. 55.4i–2).



ACTIVATING SITUATION
voices: "slash your wrists"
Core Belief
"I deserve punishment"
INTERPRETATION
"It's the voice of Satan"
AFFECT
Fear/Helplessness
BEHAVIOR
Complies/cuts wrists

FIGURE 55.4i–2. Generic cognitive model applied to psychosis.

This example helps to illustrate the importance of interpretations or thoughts about experiences, such as auditory hallucinations. It is important to stress that it is not the voice itself that leads to unwanted feelings or behaviors, but the thought about the voice. It is more distressing to think Satan is making threatening demands (Satan is a powerful, controlling, external agent) than to think voices are due to brain changes caused by illness. If the interpretation is that voices are due to illness (no power to harm, controllable, internal origin), then fear, helplessness, and risk of self-harm can be reduced. The core belief ("I deserve punishment") is provided in Figure 55.4i–2 to illustrate the importance of developing a formulation about highly charged beliefs that drive interpretations. It is typically not useful to complicate the model by including this aspect in the psychoeducation process early in therapy, although it may be added later.

Behavioral Interventions. Behavioral activation, pleasure predicting, and relaxation training techniques described above are all relevant to the older client with psychosis, and these techniques are used in essentially the same way. Particularly important treatment targets for older people with schizophrenia or other psychotic disorders are communication skills and psychosocial interactions (e.g., asking someone to share a leisure activity, making positive requests for support from friends, family, or professionals, expressing anger and assertiveness). The predominant therapeutic technique used to improve communication skills is behavioral role-play. Role plays are also useful for generating thoughts that can interfere with adaptive social interaction (e.g., "He thinks I'm dumb"; "He won't want to talk to me"; "He wants something from me"). These thoughts can then be targeted for change using thought-challenging interventions (e.g., the 3C's). Low self-efficacy and defeatist performance beliefs ("I will forget what to say"; "I will mess it up") can also be identified by using scaling techniques, where the therapist asks clients to rate their expectations for success in the role play on a scale of 1 to 10 before practicing and again rate performance after practice. The therapist can then compare these ratings to point out how people perform better than they think they will (pre–post ratings almost always increase), so clients can raise expectations for success to increase the likelihood that they will use the skills in the real world. In this way, the role-play itself can serve as a behavioral experiment to test out defeatist beliefs. By teaching new social skills while changing the defeatist thoughts that interfere with skill performance, negative symptoms and functioning can improve.

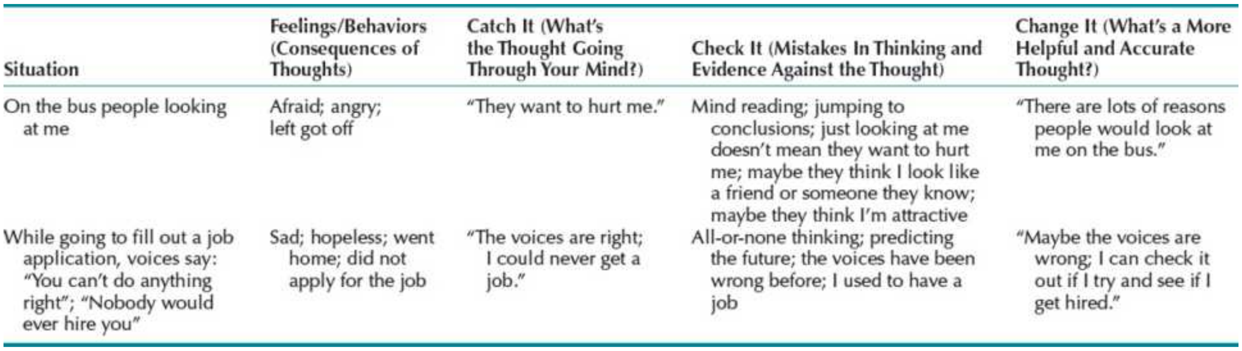
Role plays can focus on a number of topics. Clients are more motivated to learn skills when role-play topics are linked to the client's personal goals (e.g., role-playing how to ask someone to coffee if the client's goal is to make a friend). Expressing positive and negative feelings and making a positive request can be emphasized to improve the assertive, nonaggressive, clear, and comfortable sharing of feelings in social interactions. Improving everyday leisure activities and psychosocial functioning are common role-play topics for these skills (e.g., asking a roommate to change their behavior; or asking someone to go to the movies). Another common focus of role plays is on identifying warning signs of psychotic symptom exacerbation and practicing reporting these to the doctor. It is sometimes useful to make a video recording of role plays and play back the recording in session. With the help of the therapist, clients critique the strengths and weaknesses of their own performance according to a list of key skills displayed on a handout or poster board (e.g., eye contact, speech volume). Clients sometimes have little insight into the impact of their negative symptoms (e.g., low voice volume, poor eye contact, blunted affect) on their social skills until they watch themselves on video. The group therapy setting is ideal for role plays. Members with better skills model for others, and this leads both to a sense of mastery for the skilled client and an increased perception that the skill is learnable for the unskilled client. Clients can sometimes accept feedback better from peers than from therapists, and situations played between group members are more similar to in vivo experiences than role plays between therapist and patient.

Given the loss and isolation experienced by older clients, one important focus is to help clients recognize and identify support persons in their lives. Older clients with psychosis often have a difficult time recognizing that some people in their lives truly are support persons, such as health care providers, board-and-care workers, and peers. Often, clients believe that only family or relatives can act as support persons. Because many older clients with schizophrenia no longer have connections with their family or relatives, it becomes increasingly important to identify support persons and help clients to recognize that many others in their life outside of family can act as supports.

Cognitive Interventions. Thought-challenging interventions (e.g., using the 3C’s) for clients with psychosis are delivered in essentially the same way as for clients with depression or anxiety. Clients are introduced to the general concepts of CBT, including the relationship between thoughts, actions, and emotion (generic cognitive model); identifying automatic thoughts; and challenging unhelpful thoughts by examining evidence for beliefs and mistakes in thinking (e.g., jumping to conclusions, mind reading, all-or-none thinking). Through in-session discussions and homework assignments, clients are taught to identify thoughts; identify relationships between thoughts, feelings, and behaviors; and identify mistakes in thinking. Thought records are used to elucidate the relationship between situational triggers (e.g., people speaking outside the client’s room) and thoughts (e.g., “They’ve come to hurt me”) and subsequent changes in feelings (e.g., fear) or behaviors (e.g., isolation, aggression) in response to thoughts. Thoughts that lead to distressing feelings or maladaptive behaviors are labeled as “unhelpful,” and are examined for accuracy. Socratic questioning is used to help clients examine the logic of beliefs and generate more adaptive alternatives to mistakes in thinking or thoughts without sufficient evidence. The primary thoughts targeted are typically beliefs about voices (e.g., “My voices are from an external being,” “My voices have power to harm me,” “My voices cannot be controlled”), beliefs about daily events that clients use as evidence to confirm delusions (“That person on the bus was part of the conspiracy”), and dysfunctional performance beliefs (e.g., “Why bother, I will fail,” “I am too sick”) that interfere with adaptive functioning.

Using the 3C’s technique for thought challenging is particularly helpful to compensate for neurocognitive impairment that is common in older clients with severe mental illness. The 3C’s technique simplifies learning and serves as a mnemonic device to help clients remember and use cognitive techniques in everyday life. Table 55.4i–3 shows examples of a 3C’s thought record for beliefs about psychosis. Thought records like this are completed both in session and as skills practice assignments between sessions. Situational antecedents are typically first linked to the feelings and behaviors that arise in them. This is done to emphasize that clients need to use these unwanted feelings and behaviors as an alert or “red flag” reminder to examine their thinking (“Catch it”). Once the thought linked to the feeling or behavior is identified and written down, the impact of the thought in terms of emotions is rated, possible mistakes in thinking are identified, and the evidence for and against the thought is reviewed (“Check it”). If the thought does not “check out” (e.g., there is evidence the thought is unhelpful), it is replaced in favor of a more balanced, more helpful thought (“Change it”). The group setting can facilitate thought challenging because other members are often better able to notice delusional thinking and articulate logical flaws, contrary evidence, and alternative thoughts than the client, who has an emotional conviction attached to the inaccurate thought.

Table 55.4i–3.
Example of 3C's Thought Record for Beliefs About Psychosis



Situation	Feelings/Behaviors (Consequences of Thoughts)	Catch It (What's the Thought Going Through Your Mind?)	Check It (Mistakes In Thinking and Evidence Against the Thought)	Change It (What's a More Helpful and Accurate Thought?)
On the bus people looking at me	Afraid; angry; left got off	"They want to hurt me."	Mind reading; jumping to conclusions; just looking at me doesn't mean they want to hurt me; maybe they think I look like a friend or someone they know; maybe they think I'm attractive	"There are lots of reasons people would look at me on the bus."
While going to fill out a job application, voices say: "You can't do anything right"; "Nobody would ever hire you"	Sad; hopeless; went home; did not apply for the job	"The voices are right; I could never get a job."	All-or-none thinking; predicting the future; the voices have been wrong before; I used to have a job	"Maybe the voices are wrong; I can check it out if I try and see if I get hired."

To gather evidence to evaluate thoughts, behavioral experiments are conducted inside and outside of sessions (homework). For example, one common belief is that a voice is from an external agent that is omnipotent (e.g., the voice of God or the Devil). A behavioral experiment to test this belief might involve training clients in distraction techniques to stop or quiet hallucinations, such as humming, listening to music, shadowing what the voices say, watching TV, or counting. If clients can control the voices to any extent using these techniques (in session if hallucinations are triggered or at home for homework), this is discussed as evidence against the omnipotence of the voices. How can simply humming or turning on the TV control God or Satan? The following therapist–client interaction illustrates a behavioral experiment.

Pat had been experiencing some paranoia that was causing her to isolate herself at home.

P: I'm really confused because I had so many coincidences happen that I was writing them down. Then my friends will say, "Are you taking your medication"? when I tell them about what's been happening. But then they can't deny that there are so many of them and it is really weird. And then it becomes so weird that mathematically it would be like getting hit by lightning two or three times. It's just that the odds are such long shots that all this would be happening. Then I start thinking that I must be under some kind of mind control and it's preplanned because the odds of this happening couldn't possibly be this strong. So this has been difficult. This is confusing.

T: What kinds of things have been coincidences in the past few weeks?

P: Just like a matter of 2 days. What I'm thinking about or what I'm doing, the next thing I'll see it in print, or it will be said on the TV. Whatever I'm thinking about, one thing or another after another. Just like, I was thinking about hermaphrodites and people who are male and female and I open my book and it's right there. Talking about androgynous people, male and female people as I was just thinking it, and then several conversations like that came up. What I was talking about or what I was thinking happened right then and there, at that moment, and I keep trying to ignore it 'cause people have said something about free associating or something like that, too much. It just got to be too much of it happening. Either I'm at some really strong path with God or I'm under some kind of mind control. I don't know which.

T: How does that impact your life? How does it get in the way of you obtaining your goals?

P: When I feel my mind controlled, for me, I end up deciding not to move at all. Like the only way is to contain it. Like it's a disease, infection. I just feel diseased, like I have an infection. Like nobody should be near me.

T: Because we might catch it?
P: Yeah, or something like that.
T: So we could catch the coincidence disease?
P: Yeah.
T: What would happen to us?
P: You'd be in the same situation.
T: Which is?
P: Being controlled.
T: So we would feel the same way you're feeling. Well, are you feeling that way right now?
P: Yeah, pretty much.
T: What if I came and sat next to you? Can we try this out and see if I catch what you've got? How about it?
P: I don't think you would know right away.
T: How long would it take me to know?
P: Just until you start noticing those types of coincidences all happening to you.
T: How long would it take me to know?
P: I don't really know.
T: Approximately?
P: I don't know. I'm just guessing how all this works.
T: Well, would you mind? I mean, because you're going to be in therapy for several months. So do you think it could happen during that time?
P: Yeah.

The therapist sat next to Pat for the next 2 months and revisited the idea weekly that the "coincidence disease" was contagious. Over time, Pat continued to notice coincidences, but the inferred controlling nature of these occurrences decreased over time, in part, because her conviction in the belief that it was a disease diminished. This is an example of thought chaining—if others don't catch it, maybe it is not a disease, and if I don't have a disease, then the cause of coincidences is not a controlling disease. As conviction in this delusional belief diminished, Pat was willing to try more activities outside the home, which provided additional opportunities for behavioral experiments to test out possible causes of coincidences, with a focus on generating alternative hypotheses.

The following case example illustrates how cognitive-behavioral interventions can be used to address command hallucinations, paranoia, and medication adherence.

Mark is a 61-year-old unmarried Caucasian male who is unemployed and taking an art class at a local community college. He served in the U.S. Army for 6 years, from ages 18 to 24 but had not worked since his discharge from active duty. He was not in combat and denied trauma (he was trained in a logistics/support role). He was medically discharged from the military for Psychosis, Not Otherwise Specified (NOS) and received benefits income from the Department of Veterans Affairs (VA). He received care from the local VA facility, including antipsychotic medication, and was diagnosed with schizophrenia, paranoid type.

He lived in a group home in a financially depressed area of his city. He had several psychiatric hospitalizations, often stemming from physical altercations, including assaulting an individual he thought was going to hurt the pastor of his church. He was arrested but not charged with this assault. He reported frequently hearing voices, including command hallucinations, especially when he forgot to take his medications, and ascribed these assaults to the voices (“The voices tell me to stop bad people from hurting other people”). He also experienced difficulty with paranoid ideation, reporting he often thought people were watching and talking about him on public transportation and at his group home.

Mark had a strong identity as an artist, and pursued art consistently for many years since leaving the military. He sculpted using clay in his bedroom and showed his therapist pictures of his sculptures. However, he reported that the limited space in his room prevented him from working on his art consistently. He also recognized that when his symptoms increased, it interfered with his working on his art. Therefore, the consumer and therapist developed goals to increase his opportunity to practice art and better manage his hallucinations and paranoia by learning cognitive-behavioral strategies and improving his medication adherence.

Treatment involved using the 3 C's and behavioral experiments to examine thoughts about the omniscience of his command hallucinations (e.g., "They know who will hurt my friends") and medications (e.g., "It's no big deal if I forget my meds"). For example, he would *C*atch thoughts about the omniscience of his voices ("They can tell who has evil in them"), *C*heck the evidence against the thought ("They were wrong about the guy they said would hurt my pastor") and the consequences ("I get arrested when I listen to them"), and *C*hange the thought to be more realistic and helpful ("Maybe the voices are wrong"). After his conviction about the omniscience of the voices was reduced, he was more willing to ignore them and not comply with their commands to protect others in order to test whether their threats would come true. By not complying, he was conducting a behavioral experiment that produced further evidence that he did not have to do what they said to protect himself or others. He also reported that his voices were from "good spirits; maybe angels" who would warn him about "people with evil in them." The fact that he thought the voices were benevolent and might protect him from harm contributed to poor medication adherence because he did not want to take medications that quieted or eliminated the voices that he perceived as helpful. The therapist used Socratic questioning to challenge these beliefs about the voices as benevolent and omniscient external agents:

T: You mentioned that you have noticed that the medications can make the voices go away, right?

M: Yes, I have noticed that.

T: That makes me a little confused, though. How can something you put in your body—medications that change your brain chemistry—make angels or something outside of your body stop talking?

M: Well, I'm not sure but it does.

T: But does it make sense that a chemical inside you could change an angel or some kind of powerful supernatural spirit? How does that work?

M: I don’t know but I get nervous when it’s been a while since the voice has given me any warnings or told me who to watch out for.

T: I can see how you might want to stop taking the medication for a couple of days when you get nervous about that, so the voices might come back, but does it make sense that medications would make angels or spirits come and go? What if the voice isn’t from an angel or spirit? What if it is from inside you and not an outside spirit? That would help explain why changing your brain chemistry can stop it. What do you think about that possibility?

M: Well, that part adds up, I guess, but I’m just not sure.

T: And we already discovered that the voices are not always correct about who is dangerous. That also makes me think the voices are from you rather than an angel because people are more likely to be wrong about things than angels. We all make mistakes, but angels probably don’t.

CLINICAL ISSUES

Cognitive-Behavioral Therapy and Medications

The use of CBT forms one part of a package of care that often includes the use of medications, where relevant and appropriate, as well as other services (e.g., case management, vocational rehabilitation, couples/family therapy). This is particularly true for psychosis. For depression, meta-analyses of CBT compared to antidepressants indicate that effects are similar (d = 0.35), and that response to CBT among older adults is similar to effects seen in younger adults. A meta-analysis including head-to-head comparisons of antidepressants and CBT in older adults found no differences between treatments, but the authors concluded the number and quality of studies were too low to make definitive conclusions. Although older adults report a preference for talk therapies over medications, the two are often prescribed together. This generally means that cognitive therapy is used alongside medication in a synergistic way, such that CBT improves medication adherence and medication controls acute symptoms that might interfere with CBT. It is recommended that, if the CBT therapist is not the prescriber, a two-way release of information be obtained from each client in order to facilitate continuity of care and communication.

Individual versus Group Format

There are several advantages to using these interventions in a group format. As noted above, group CBT is one of the first-line recommendations for the treatment of depression in older adults. Groups are widely used in mental health clinics (increasing the likelihood that these interventions will be acceptable to such sites); treatment can be provided for a greater number of clients in groups than could be accomplished in individual sessions; groups can impact social support systems and allow the practice of communication skills; groups provide a shared identity with others (i.e., healing power of connections with others, “me too” and “not alone” influences); confronting or observing others in groups may provide better insight into one’s own symptoms and skills deficits, and groups can provide social reinforcement for change. One important difference between group and individual CBT formats is that groups tend to emphasize skills training over detailed case formulation. There is less time in groups to fully explore the unique content and history of each client’s presenting concerns in developing a formulation. There is also greater flexibility to tailor therapy to the individual needs of the client in individual therapy.

Goal-Setting Challenges

Setting goals for therapy with older clients who have been ill for decades can present unique challenges encountered less frequently with more recent onset clients. Particularly for older clients who have had a chronic or recurrent course of a disorder, there may be low expectations for treatment success. Information-processing biases also often lead to a focus on failures and ignoring past achievements. By acknowledging a goal, older clients must accept the risk of yet another failure. This risk assessment is often exaggerated into risk of symptom exacerbation and rehospitalization. For patients with psychosis in particular, by this stage of illness, older people have also been informed that they have a severe, chronic brain disease with little hope of recovery. Older clients have had much less exposure to modern recovery and psychosocial rehabilitation models that have only recently begun to transform health care systems to focus more on strengths and hope for functional achievement. Hopelessness in providers can be passed on to older chronic clients. While not as potentially profound as psychosis, other depressive and anxiety disorders that have followed a chronic course can also facilitate hopelessness for change.

These factors can create challenges for eliciting a goal for therapy. Setting a treatment goal may require patience across several sessions. Cognitive therapy tools can be used to address dysfunctional performance beliefs, negative expectancies, and ignoring the positive and other attributional styles that can lead to hopelessness and reluctance to set a meaningful goal. Older clients may also initially offer a goal that they have learned providers want to hear (e.g., "I want to take my medications more regularly"), rather than a more personally meaningful goal. Goals may need to be revised as more meaningful goals emerge. It may be useful to ask clients to recall a time when they were functioning better in the past or imagine a time years in the future when they are much better and ask about daily behaviors. Ask, "What would you be doing if you weren't feeling this way"? This can stimulate a helpful discussion about desired, meaningful functional behaviors (relationships, volunteer work, leisure activities). The key is to get a personally meaningful goal.

We have found it most helpful to focus on specific, functional behavioral goals (increasing socialization, relationships, leisure activities, living skills to promote independent housing, school, work/volunteering) chosen by clients. Emotional or symptom goals (e.g., "I want to stop being sad" or "I don't want to hear voices") are less helpful unless framed in terms of their impact on functional behaviors. For example, one can ask, "How would you know you weren’t sad anymore? What would you be doing”? The response is often something like, “I would be getting up and doing more things.” The therapist can then ask what things, and frame the functional behavior as the goal (e.g., doing things with friends, taking a class). Goals should also be specific and stated as attainable behaviors. For example, the therapist can ask, “How will you know the goal has been achieved? What will you be doing differently each day if you achieve the goal”? The therapist’s goal is to help older clients set meaningful, realistic, attainable, specific goals stated in terms of functional behaviors.

Importance of Homework

One goal of CBT is to provide skills that generalize and are used by the client outside therapy in everyday life. To that end, treatment includes both skill practice in sessions as well as homework assignments. In-session practice is a crucial means by which clients understand the sometimes difficult concepts in this intervention. Homework assignments are crucial for generalizing these skills to the “real world,” but homework adherence can sometimes be challenging. The term “at-home practice” is often used, rather than “homework,” to emphasize the importance of practice outside of sessions and to reduce the negative connotation associated with “homework” assignments back in school days. Adherence to at-home assignments can vary considerably between clients. Older clients in particular may have expectations that the active treatment factor in therapy is disclosure rather than practice, and this can interfere with willingness to complete outside assignments. To facilitate homework completion, the therapist guides, instructs, and explains the rationale for completing home activities, and activities are practiced in session. The therapist goes over several examples so that clients can more easily do the remainder of the assignment at home. An analogy with learning to play a musical instrument can be used to stress the importance of practicing skills (e.g., “Just like learning to play the guitar: if you only practice when you are at your music lesson, you won’t learn songs as fast as if you practice in between lessons”). Principles of operant conditioning are also used to facilitate homework completion (e.g., positive attention and praise to those who complete homework). The therapist makes clear to clients that homework completion is expected and failure to complete assignments is the topic of thorough problem solving to help the client do a better job next time. The authors have had success in obtaining 80% homework completion in 80% of older clients with schizophrenia in their CBT for psychosis groups. Previous research with other populations has shown that CBT incorporating homework assignments helps clients improve about 60% more than those in treatment without homework.

Indications

CBT treatment targets may change as people age. There is evidence that CBT is efficacious for a range of disorders in older adults, including depressive disorders, anxiety disorders such as panic disorder and social phobia, and psychosis. In addition, while there are a number of pharmacologic treatment options available, clients often desire psychotherapy options. Of note, although positive symptoms tend to be reduced in older clients and may often be fairly well controlled through pharmacologic treatment, these clients commonly still experience negative symptoms and severe psychosocial functioning deficits, which are important treatment targets of CBT in older people with psychosis.

Contraindications

A number of factors may interfere with psychotherapy overall. For all older adult clients, it is important to assess the possible causes of many psychological symptoms, such as fatigue, appetite, and sleep disturbance, because medical comorbidity and normal age-related changes may contribute. Comorbidities, such as substance abuse and medical illness, may interfere with attendance in CBT. This barrier can be overcome by conducting therapy in the client’s home or senior center in the neighborhood, in the presence of a caregiver, by finding a resource for transportation, or by providing treatment via videoconferencing. In addition, CBT interventions can include comorbidities as treatment targets (e.g., reducing substance use through harm reduction techniques, improving health status through addressing obstacles to treatment adherence). Poor insight (awareness of having a mental illness that requires treatment) is prevalent in some psychotic disorders and predicts poor course of illness and functioning. There is also some evidence that insight moderates treatment outcome in CBT for psychosis. Severe disorganization in psychotic clients presents a number of challenges to the logical, hypothesis-testing process of cognitive therapy, but some of these clients succeed despite thought disorder, and there is no clear data on the impact of this potential barrier. The authors have found that disorganization frequently fluctuates, as well, so a more behavioral intervention focus can be used until clients are more able to communicate more linearly. Neurocognitive impairment is often assumed to interfere with CBT, but this assumption may not always be accurate. Progressive dementia will likely interfere with CBT and neurocognitive impairment does predict poorer outcome in serious mental illness, in general, as well as treatment outcome in psychosocial interventions. However, there is no evidence that neurocognitive impairment reduces the benefit of CBT in serious mental illness relative to standard pharmacologic care alone. That is, even participants with moderately severe neurocognitive impairment show added benefit from receiving CBT plus pharmacotherapy, relative to receiving only pharmacotherapy. With little clear evidence about which clients will and won’t benefit from CBT, the authors recommend that willing clients be given a chance to succeed. The biggest barrier to success may be provider hopelessness; clients who are never referred for CBT because they are thought to be too old or too impaired in some way can never succeed.

Cognitive Therapy versus Cognitive Remediation

Two broad categories of cognitive interventions have been developed: Cognitive remediation, which focuses on rehabilitation of specific cognitive functions (e.g., memory, attention), and CBT, which trains participants to use metacognitive strategies to identify and challenge unhelpful or inaccurate thoughts. These areas of intervention have several factors in common and may lie on a continuum from more “molecular” to more “molar” cognitive rehabilitation approaches, but they are often incorrectly equated. At one end, cognitive remediation targets specific problems of neurocognitive processing, and at the other end, CBT targets more global cognitive constructs, such as thinking and self-concept. Clients with severe mental illness typically have neurocognitive impairment and may benefit from cognitive remediation interventions and/or medications that attempt to improve neurocognition. Combining these interventions may enhance outcome in CBT, but cognitive remediation is not cognitive therapy.

RESEARCH AND EVALUATION

Depression

Recent studies indicate that CBT is as effective as pharmacotherapy for treatment of major depression. A meta-analysis of treatments for late-life depressive disorders found that pharmacotherapy and psychotherapy (most often, CBT) were similarly effective in terms of symptom reduction. The American Psychological Association (APA) depression treatment guidelines for depression listed group CBT as a recommended treatment for older patients with depression, and individual CBT, either alone or in combination with pharmacotherapy, as a conditional recommendation if a first-line recommendation is not available or acceptable. There is currently little evidence of differential effectiveness of pharmacotherapy versus psychotherapy in the treatment of major depression and related mood disorders, and therefore, recommendations for treatment should be based on factors such as patient preference and possible medical implications. In particular, older clients may have more difficulty with side effects of medications or have concerns about interactions with other medications, making CBT a particularly appropriate option. Finally, treatment preference studies overwhelming suggest that older adults prefer talk therapies over medications, so these treatments should be accessible in settings that serve older adults.

Anxiety

There are fewer well-designed studies available on CBT for late-life anxiety disorders, especially trials comparing CBT with pharmacotherapy for late-life anxiety disorders, and the combination of medication and psychotherapy has not yet been formally tested in an adequate clinical trial. Most randomized, controlled trials have compared CBT to other psychotherapies or control conditions, and most have examined generalized anxiety disorder or enrolled clients with a range of anxiety diagnoses without differentiating between them. A recent meta-analysis of 14 randomized controlled trials (RCTs) for generalized anxiety disorder (GAD) found that CBT was superior to no treatment or treatment as usual, but there was insufficient evidence to draw conclusions in comparison to other active treatments. An earlier review suggested that medications, particularly selective serotonin reuptake inhibitors, appear to be more effective than psychotherapy as an acute treatment for late-life anxiety disorders. In general, results of psychotherapy trials suggest that CBT has some benefit, although clients do not on average reach a symptom-free status. Cognitive-behavioral interventions that include relaxation training appear to be more effective than those without. For older individuals who refuse to take medications or for whom they are contraindicated, relaxation training may be the most effective component of a behavioral treatment, but direct comparisons have not been conducted. At this point, there is need for better-controlled trials of CBT for specific anxiety disorders, and in particular, trials that compare CBT with pharmacotherapy as well as trials examining combined pharmacotherapy and psychotherapy, especially in older clients. Nonetheless, the current literature indicates that CBT is a potentially useful approach for older clients with anxiety disorders.

Schizophrenia

Only a handful of studies have examined any form of psychotherapy interventions for older people with schizophrenia. Over 50 clinical trials of CBT for psychosis have been conducted with middle-aged and younger people with schizophrenia. These clinical trials found significant improvements in hallucinations and delusions (typically the primary treatment target), community functioning, negative symptoms, social anxiety, and mood. Available clinical trials, however, have concentrated on the adult population up to 65, so their generalizability to older groups needs to be considered cautiously. The authors developed, manualized, and conducted clinical trials of a novel psychosocial rehabilitation intervention called cognitive-behavioral social skills training (CBSST) in older people with schizophrenia (mean age 58). CBSST combines techniques from both CBT and social skills training to target the multidimensional deficits that contribute to disability in aging people with schizophrenia. In four separate clinical trials, the authors have found significant improvements in social skills and community functioning in CBSST relative to standard care and relative to a goal-focused supportive contact control group, and these gains in functioning were maintained at 1-year post-treatment follow-up. A recent review of psychosocial interventions for improving functioning in middle and older age clients with severe mental illness concluded that the strongest evidence was for skills training interventions that incorporate either cognitive or behavioral techniques and use a group format. However, there is clearly a need for expanded research, particularly in the older population.

55.4j Family Intervention and Therapy with Older Adults

LAUREN N. DECAPORALE-RYAN, PH.D., ANN ELIZABETH CORNELL, PSY.D., C.E.A.P., JESSICA GOODMAN, PH.D., AND CAROL ANN PODGORSKI, PH.D., M.P.H., M.S.

Over the past decade, demographic trends have altered the composition of the older adult population in substantive ways. The older adult profile began to change in 2011, when the Baby Boom generation, currently one-quarter of the U.S. population, began to turn 65. With an increase of nearly 35% over the past decade, nearly 17% of the population is currently over age 65, with racial and ethnic minorities constituting 23%. Older adults are now comprised of two generational cohorts—the "traditionalists" born before 1946 and the "Baby Boomers" born between 1946 and 1964. These groups differ in terms of experiences, values, attitudes, and preferences. The Baby Boom generation is likely to have families that are more geographically dispersed, experience more divorces, have fewer biologic children, amassed more blended families, and are increasingly living in multigenerational households. Baby Boomers are more likely to be healthier, but with the increased longevity of “the traditionalists,” 70% of those over 65 have functional limitations. Similar to previous generations, their needs are met predominantly by families and friends.

The infiltration of Baby Boomers into the over-65 population has also triggered shifts in health care preferences and in relationships with medical professionals. This information-seeking, authority-challenging generation was instrumental in forming and shaping the movement toward consumer-directed health care. In addition, the newest older adults are more accepting of the notion of “mental health” and less resistant to seeking mental health care. According to the Substance Abuse and Mental Health Services Administration (SAMHSA), 14% of those over 65 had any mental illness in 2019, and 47% of them received mental health services. A growing body of evidence indicates that older adults generally accept and are satisfied with telegeropsychiatry services. Thus, the demand for mental health services among older adults is increasing, and the nature of the older adult patient–mental health clinician relationship will continue to evolve to reflect multiple generational and sociocultural influences.

Other changes in health care delivery approaches have increased the need for clinicians to hone their skills for working with families. The Patient Protection and Affordable Care Act, passed in 2010, placed a greater emphasis on integrated care through establishment of federally qualified patient-centered medical homes. According to the Agency for Healthcare Research and Quality, “integrated behavioral health care” is the care a patient experiences as a result of a team of primary care and behavioral health clinicians, working together with patients and families, using a systematic and cost-effective approach to provide patient-centered care for a defined population. Another widely adopted health care practice affecting health care delivery is the emergence of patient- and family-centered care. In 2012, influential organizations, including the Institute of Medicine and The Joint Commission, adopted patient-centered care as a fundamental aim toward enhancing quality of care. An outgrowth of patient-centered care has been the emergence of family-centered care. The primary goal of patient- and family-centered care is to promote patients and families as active participants in care and decision making by treating them with respect and dignity; sharing complete and unbiased information in ways that are useful and affirming; and encouraging their participation and collaboration. A current nationwide initiative developed to improve care for older adults by focusing, in part, on what matters most to them is the Age-Friendly Health System, a program launched by the John A. Hartford Foundation and the Institute for Healthcare Improvement. Inherent in all of these efforts is the need for clinicians to be skilled in building and navigating relationships within families, as well as among families and health and social service providers. The adoption of integrated health care and patient- and family-centered care have created a shift in health care delivery from *serving* patients to *partnering* with patients and families.

Older adults today often have modified extended families as byproducts of single-parenthood, multiple marriages, and blended families. While families may span great geographical distances, they nevertheless are often able to mobilize support between and among older adults, their adult children, and other family members as needed. Those at greatest risk for isolation include Hispanics and men, who more often have fewer connections and report that they do not receive the social or emotional support that they need. When older adults do not have relatives nearby, they often form intimate social bonds with friends, neighbors, or others who are not related by blood or legal ties. Thus, an appropriate definition of the aging “family” must be flexibly inclusive.

Family intervention and family therapy are not one and the same. Family intervention is the process of bringing together two or more family members to address problems causing distress or impairing function. In late-life families, family intervention involves educating about the unique medical and psychosocial challenges of aging and their effects on the older adult and family. Family intervention also may involve facilitating communication among family members regarding age-related concerns, but it does not involve intentionally changing the way a family functions. In contrast, family therapy is an intervention that brings family members together to alter the family structure or functioning, thus facilitating adaptation to the challenges of aging. Family therapy is considered when assessment reveals problems in the family's pattern of organizing itself or interacting in response to age-related concerns and when family members explicitly agree to engage in a deliberate process of change. The decision to engage in family therapy typically reflects an acknowledgment that the family's natural adaptive capabilities are overwhelmed by the nature or intensity of challenges or perhaps that the family does not have the knowledge or skills necessary to deal with the situation at hand.

HISTORY

Family therapy with older adults has its roots in two distinct but overlapping theoretical approaches to the understanding of human behavior. First, family systems theory maintains that the family functions as a network of interconnected elements so that change in any one individual's status or behavior will affect that of others in the family. Accordingly, there is a natural tendency for the family system to attempt to maintain balance or homeostasis. Second, family life cycle theory views the family system as moving as a unit through time, encountering both predictable, normative transitions and unique, family-specific challenges. Life events such as a change in health or functional status, loss of a loved one, or remarriage of a parent challenge the family's natural homeostatic mechanisms and require a dynamic process of adaptation in order to reestablish equilibrium. The clinician working with aging families interprets the behavioral or emotional problems of an older adult as indications that the family system is struggling with transitions or crises associated with the life cycle stage. The therapist's task is to help family members organize or reorganize their resources and family roles in a manner consistent with the life cycle challenge they are confronting.

Although much of family developmental and systems theories have focused on the first half of the family life cycle, more recent depictions consider the structural and cultural heterogeneity of aging families. Life cycle theorists now consider late-life families as being comprised of blended families, families with single parents or grandparents raising children, and families of gay, lesbian, and transgendered individuals. Moreover, life cycle theories have started to include descriptions and differentiation of developmental tasks during the second half of life, including adjustment to retirement, attainment of grandparenthood, coping with loss and illness, and passing on family legacy. Recent theoretical accounts also address stages of family reorganization when its older adults decline due to progressive illnesses. Whether voluntary or involuntary, shifts in power within or between generations often create instability in families which often culminate in reorganization of roles and responsibilities. Such new models help therapists frame interventions that are appropriate to the tasks associated with a family's needs for adaptation.

THEORETICAL ISSUES

A variety of specific approaches to family intervention and therapy with older adults have their foundations in systemic and life cycle themes. The contextual approach emphasizes family ethics and seeks to help families balance the intergenerational "ledger" so that patterns of caregiving are congruent with the family's history and resources. The developmental-interactional model categorizes late-life family problems as situational, transitional, or chronic, integrating life cycle and structural-strategic approaches to help the family frame solutions to the problems in a manner consistent with their unique history and style. Recent approaches to grief therapy combine elements of family systemic, symbolic interactional, and narrative approaches to facilitate family storytelling, or "meaning making," thus strengthening family ties among the living as well as helping families redefine their relationships with those who have died. Cognitive behavioral therapy approaches, such as problem-solving therapy, are increasingly being used with older adult couples, caregivers, and families alike.

Strength-Vulnerability Model of Health and Illness

The strength-vulnerability model postulates that the mental health of individual family members is determined over time by the interaction of individual and family life cycle processes. Although not empirically validated, this clinical approach builds on systemic and life cycle theories, as well as research linking health outcomes to a variety of personality and psychosocial factors. Specifically, the model focuses on strengths and vulnerabilities at the level of the individual older adult (e.g., biologic health, personal themes, and individual life history) as these interact with health-enhancing and risk factors at the larger levels of family and other social systems (e.g., family events, themes, relational processes).

According to this theory, attachment and caregiving form the bond of affection between family members that must be present as a foundation for the development of other interpersonal processes in the family. Communication is the development of shared meaning between family members. This process includes sharing important themes and content, as well as constructive communication of affect. Shared problem solving is the ability to develop solutions to problems and carry them out cooperatively. Implicitly or explicitly, this process involves the delineation of family roles as they pertain to decision making and authority. Mutuality involves a long-term commitment to the relationship and the dynamic ability to reinvent the relationship over time in the face of life cycle transitions. These processes are thought to develop sequentially in families so that some element of attachment and caregiving is necessary for effective communication. Likewise, some effective communication is needed to successfully and collaboratively solve problems. Finally, effective problem solving is a prerequisite to the ability to reorganize and reinvent family relationships with mutual understanding through periods of crisis and life change. The epigenetic pattern is actually circular and dynamic, involving periodic reworking of various relational abilities rather than being a linear progression through a series of discrete stages. Thus, if late-life transitions and crises are met with successful mutuality, attachment and caregiving will take a new and strengthened form. With an unsatisfactory resolution of change, the bedrock of attachment and caregiving will be undermined.

TECHNIQUES

Family therapists are tasked with developing interventions that are congruent with the family's stages of relational and life cycle development. Thus, a detailed family assessment is the foundation upon which family interventions are developed.

Assessment

During the initial sessions, the therapist evaluates the family's unique strengths and vulnerabilities, including, at a minimum, the following key points, which can be easily remembered using the acronym LIFE: *Life cycle transitions* faced by the family and by individual family members—for example, raising children, job demands, financial stressors, retirement, grandparenthood, loss of a spouse, or onset of chronic or degenerative illness; *Individual roles* assumed by family members—for example, caregiver, breadwinner, matriarch or patriarch, and scapegoat; *Family relational processes*—that is, the quality of attachment or caregiving bonds, communication, and problem solving; and *Ethnic or cultural factors*, including spiritual beliefs and practices impacting the family's functioning.

Levels of Intervention

The family assessment determines whether the intervention will most appropriately be psychoeducational, with a focus on providing information pertinent to a problem or illness, or therapeutic, with a goal of changing the family's structure and quality of relational functioning. Several levels of therapy are considered, each reflecting work at successively deeper strata of family relational functioning. These levels serve as general guidelines for considering the type and intensity of treatment appropriate for a particular family.

Level One: Psychoeducational Intervention and Community Referral. Families who exhibit solid attachment bonds, open communication, and good problem-solving skills do not require ongoing therapy but, rather, benefit from brief education regarding a specific late-life issue. For example, when older adults develop new medical disorders, such as Alzheimer disease, families benefit from information specific to the disorder and its management as well as referral to community agencies and support groups. Families can usually organize themselves for effective problem solving regarding the care and support of the older adult. Despite their potential benefit, only a small percentage of families avail themselves of these resources. In the case of chronic, deteriorating illnesses, however, the family may benefit from brief, intermittent contact with the therapist at those transition points when the disease worsens or they acknowledge readiness to face the next challenge. Such families typically do not require regular, ongoing professional support.

Level Two: Restoring Effective Problem Solving. Families often have solid, positive bonds of attachment with good communication skills and histories of effective problem solving, yet they temporarily are overwhelmed by the intensity and unfamiliarity of a late-life problem, such as severe illness, functional decline, or the approaching death of a previously capable family member. In these cases, effective problem solving may be temporarily stymied because of paralyzing grief reactions or sudden disequilibrium in the previously stable family structure. The family may need to reorganize lines of authority and decision making to bring them into accordance with the demands of a later-life transition. For example, families typically go through a natural transition during which the younger generation gradually assumes more of a role in an older adult’s affairs. This reciprocal process requires not only commitment and involvement on the part of the younger family members, but also willingness on the part of the older adults to allow this transition to occur without becoming overly demanding, resentful, or needy. Therapists recognize that the history of parental authority and caregiving continues to influence intergenerational dynamics well beyond the actual parenting years.

One common example of family difficulty at this level is when the matriarch or patriarch experiences a decline in health or cognitive capacity, throwing the surviving family members into a state of disequilibrium. The spouse and adult children in this situation are unaccustomed to assuming decision-making authority and typically need assistance in reorganizing family roles. After receiving clear and direct information about the status of the older family member, reflecting on the meaning that they as well as the older adult assign to this situation, and having an opportunity to grieve these changes, adaptive adult children at this level of relational development can often mobilize their resources to solve family problems.

Level Three: Improving Patterns of Communication. Some families who care deeply about each other and have solid bonds of attachment communicate little about serious problems. Some may have a history of arguments and resentment stemming from past crises. Some family rules prohibit the exchange of certain emotions or information. Others have been able to function with little overt communication in earlier stages of the life cycle, because they were not confronted with major loss or illness. When faced with challenges of aging, they have difficulty developing a common understanding of the problem and thus cannot work collaboratively to find and carry out solutions. Families at this level benefit from active modeling of open, positive communication. Basic communication techniques, such as active or reflective listening, can greatly benefit these families, as can clear and consistent modeling of how to talk openly but respectfully about the challenges before them.

QUESTIONS FOR THE PATIENT

Communication and Problem Solving. How is information about important events shared in your family? Who typically participates in making decisions? Is one person responsible for making a final decision? Is anyone excluded from important family decisions? How do family members resolve conflict when it occurs?

Family Roles and Expectations. What role does the older adult play in the family? Who are the individuals responsible for caring for the older adult? Who, if anyone, is primarily responsible for providing care? Has the older adult appointed a health care proxy? Does anyone live with an older adult? How much time in person, on the phone, or otherwise is each person able to contribute to the older adult's care? Who, if anyone, is responsible for helping older adults with their activities of daily living (ADLs)/instrumental activities of daily living (IADLs)? Are you aware of local resources that may be able to help the older adult? What have your experiences with the medical system been like in the past? What are your expectations for the older adult's care? What do you know about their end-of-life wishes if the older adult is unable to express them?

Level Four: Improving Bonds of Attachment and Caregiving. Families with negative, weak, or ambivalent bonds of attachment typically have a history of conflict, marginal functioning, or insufficient nurturance between family members. In some cases, adult children who were abused or neglected as children struggle to take care of the one they perceive as a former abuser. Such families are at risk for elder abuse, and some may require referral to professional caregivers or long-term care facilities. In many instances, however, techniques, including family life review or contextual family therapy interventions, can be used to induce empathy for the older adult's position, thereby decreasing negativity, increasing feelings of safety, and making it possible to forge more positive bonds of affection between the generations.

Family life review is the process of bringing multiple generations together to weave a coherent intergenerational family story. Typically, this process is facilitated by constructing a family genogram, which is a graphic, multigenerational picture (family tree) that encapsulates family history, structure, and relationships over time. The therapist encourages the family to begin with the family of origin stories of those in the oldest generation, gradually working down through the themes and experiences of subsequent generations. Learning about their upbringing, cultural context, and early family circumstances often gives younger family members a different, more empathic perspective. Some children or grandchildren then can establish more mature "adult-to-adult" relationships with them, rather than continuing to relate solely from the vantage point of children whose needs for nurturance and care were unmet.

CLINICAL ISSUES

Clinical Applications Across Health Care Settings

The strength-vulnerability model of health and illness is an appropriate framework to use for conceptualizing and delivering patient- and family-centered care to families with older adults in multiple therapeutic contexts. Applications of this model across health care settings in which mental health clinicians practice are described here.

Outpatient Psychiatry

The majority of older adults with behavioral health symptoms receive mental health services through some type of outpatient setting. Outpatient services are provided in a variety of settings, including private practices, community mental health centers, hospital-based clinics, or programs embedded within nonprofit organizations. Geriatric specialty clinics offer a range of services, including psychotherapy, social work, and case management, which can help to support the work of mental health clinicians. Many older adults gain access to psychiatry through consultation models that exist in some integrated care settings. In this model, primary care physicians and psychiatrists are colocated, and physicians are able to consult with a psychiatrist onsite, or they can refer patients within the practice to see the psychiatrist for an evaluation and treatment recommendations. Occasionally, independent living communities may help organize or provide access to psychiatric services for residents. In any type of outpatient setting, psychiatry can play an important role in assessing and identifying family, social, contextual, environmental, and physiologic factors that can support or exacerbate the patient’s mental health issues.

In any outpatient setting, clinicians should focus on: conducting a comprehensive evaluation of mood, cognition, and functional capacity; paying particular attention to issues that may impair the patient’s ability to perform ADLs or IADLs; gathering information about the patient’s social support network including family, friends, and community resources; provide psychoeducation on the identified mental health issue and how such issues may impact the older adult’s ability to care for themselves; identify potential barriers to treatment including financial resources, transportation, housing, and access to health care; and gather information about the older adult’s physical health and collaborate with the patient’s physician or other members of the health care team. As with any population, there are challenges involved when treating older adults in an outpatient setting. The most salient issue is the constraint of time. Completing a comprehensive evaluation that includes an assessment of family history and function within a 30-minute intake poses a formidable challenge. The medical comorbidities with which many older adults present often add to the complexity of the assessment and treatment planning processes.

Mrs. D was an 89-year-old, Caucasian, widowed female of Italian descent, referred to an older adult outpatient specialty clinic for symptoms of depression and anxiety. She reported a long history of depression and anxiety and estimated that her current symptoms began six months ago when her family decided she could no longer live alone after she gave herself food poisoning. This incident made the family realize how difficult it was for the patient to complete her ADLs due to arthritic pain, decreased mobility and stamina, and an unstable gait.

The patient's family consisted of her four daughters, three of whom lived locally. Each of the daughters contacted the psychiatrist separately to provide information about the patient's mental and physical health. During the intake, which two of the daughters attended, the patient was irritable and expressed her concerns about her eldest daughter's ability to care for her properly. The daughters argued openly about the patient's needs until one daughter left. As the psychiatrist gathered more information it was clear that this family had deep emotional wounds that negatively impacted all of their relationships. The daughters felt "burnt out" and stated that they cared for their mother "out of obligation, not love." Two of the daughters reported having been physically and emotionally abused by the patient.

Based on the strength-vulnerability model, this family is best described as having negative, weak, and ambivalent bonds of attachment (Level 4). Communication and, therefore, problem solving were ineffective. They were unable to make decisions as a group and each wanted to be in a position of authority. Working on the hypothesis that the family needed to work on a family life review to encourage more positive family communication, the psychiatrist referred the patient and her family for family therapy. Meanwhile, the psychiatrist took active steps to create opportunities for positive communication and problem solving. The patient and her daughters were asked to create a list of activities with which the patient would require assistance, and the degree to which she would need assistance. The psychiatrist provided guidance regarding the ADLs and IADLs to consider. Family members were encouraged to review the list and to decide which type of help each was able to provide. An information system including the patient's needs, medical status, and psychological status was devised and shared with all family members on a biweekly basis. The combination of these interventions helped the family learn how to communicate and problem solve more effectively while working with a counselor to improve the overall quality of the attachment bonds.

Inpatient Medicine Service

Over 40% of older patients seen in the emergency department are admitted to the hospital. These patients not only face physiologic problems but also suffer psychosocially, which is even more likely if diagnosed with chronic medical conditions. Estimates suggest that nearly 75% of older adults who enter the hospital functionally independent will leave requiring support with ADLs and many of them will return to the emergency department for repeat admissions. The need for adequate discharge planning and improved long-term disposition is dependent upon assessment of their holistic needs, including functional status, cognitive capacity, mood, and social support. Though hospitalists are often relied upon to conduct such assessments, their time is limited and many have not been trained extensively in the unique needs of geriatric patients or in psychiatric interview techniques. Psychiatry can play a supportive role in acute medical settings by offering consultation to the medical team and to patients and their families, thereby ensuring a safe transition from hospital to home or an alternate placement. In addition to this consultative role, psychiatrists offer valuable help to patients coping with biopsychosocial changes and transitions.

To do this work most effectively, it is important to utilize a patient- and family-centered approach that recognizes the older adult as an activated patient who wishes to participate in the development of treatment and discharge plans. Psychiatry supports the patient and family by recognizing the patient's preferences, helping them to make informed decisions, listening to their concerns and questions, providing them with education about the mind–body connection in the context of acute medical illness, and informing them of available resources. In an acute medical setting, psychiatrists can anticipate conducting a comprehensive assessment of mood, cognition, and functional capacity, paying attention to the illness story and changes that have occurred as a result of hospitalization; evaluating the patient’s social supports and availability of caregiving; providing consultation on medication management of symptoms, including labile mood, poor appetite, and insomnia and identifying resources to address other patient and family needs.

Conducting a comprehensive assessment with an older adult in the medical setting is similar to the health assessments psychiatrists conduct with adult patients, but requires additional detailed attention to the functional capacity of the patient as outlined in Recommended Questions for the Patient.

Recommended Questions for the Patient

PERSONAL/SOCIAL FUNCTIONING. Where do you currently live? Where will you go after discharge? Where do you hope to go? Is there anything you (patient/family) worry about regarding discharge? Is there anything about the physical layout of your home that concerns you? Prior to your hospitalization, did you require help with ADLs/IADLs (specify each)? How does your illness limit your ability to engage in routine activities? Who has helped you in the past when you’ve become ill? Who will help when you go home? Are you the caregiver to a loved one (and, if yes, who will help you care for them now)? Have you experienced any other transitions or changes recently? Do you have transportation needs? Do you have access to and/or are you able to use a computer or your phone to connect with telehealth services?

EXPERIENCE OF PAST AND PRESENT ILLNESS. Have you recently been hospitalized? What caused you to become sick enough to return to the hospital? Why were you readmitted? What could have been done differently before you left the hospital last time? What has gotten in the way of you taking care of yourself? What needs to happen while you are here/before you are discharged so that you remain healthy? How well do you follow medical recommendations? What gets in the way of taking care of yourself?

Psychiatry is also often tasked with providing psychoeducation to the treatment team, patient, and family. It is well established that a patient's physical functioning, number of comorbid medical conditions, and history of depressive episodes can result in comorbid mood and anxiety disorders in late life. When patients and families receive adequate information it serves to validate the experienced change in mood, normalizes the experience of lability, acknowledges the mind–body connection, explains the anticipated recovery from changes in personality and mood, and provides patients and families with hope for improved quality of life following illness.

Clinicians can also provide supportive listening, paying attention to the patient and family experience of illness, the subsequent loss of function and independence, and fears of death. Through dialogue the consultant can identify whether the development of improved coping skills and implementation of relaxation techniques at the bedside would be beneficial. The family draws support from acknowledgment that they are also impacted by the hospitalization. Caregivers are described as "invisible patients," as their needs are often not assessed or addressed in health care. They report that hospitalization causes disruptions to their everyday routines, distress, and difficulty meeting their own personal needs. Caregivers are often older themselves and require assistance with their own care in order to best serve the one needing care. Consideration for caregiver burden, burnout, risk of elder abuse, and determination of the family's capacity to provide care are essential components of a discharge plan.

Mr. B was a 76-year-old man of Jamaican descent. He was hospitalized following a stroke, suffering from dysarthric speech and changes in mobility. His wife of 47 years reported that their youngest daughter, who lived with them, had been admitted to the same hospital that week for management of congestive heart failure. Their six other children expressed concern about their mother's capacity to care for both her husband and daughter postdischarge.

The patient was very tearful throughout his hospitalization. Mrs. B was increasingly distressed by the patient's continued dysarthric speech, which was exacerbated by his tearfulness. She wanted to know what was "wrong" with him, articulating that he had never suffered from such a labile mood and expressing uncertainty about how best to support him. Though the Medicine service recognized the patient's symptoms as common following a stroke, they did not have adequate time to address Mr. or Mrs. B's distress or understand it fully. The Medicine service requested a consult from Psychiatry to better meet the patient's and family's needs.

A psychiatry resident met Mr. B, asking questions about his medical experience. Mr. B expressed regret that he had not been a more spiritual man, noting that his survival would not have been possible without religious intervention. His wife frequently nodded her head, saying little except to occasionally repeat what Mr. B had said when concerned the resident had not understood him. Amidst the couple's sobbing, the resident asked, "How much do you understand about why you feel this way?" Again, Mr. B noted religious reasoning. The resident was able to validate the family's tie to spirituality while simultaneously providing psychoeducation about the mind–body connection and the impact of stroke on mood.

Mr. B heard this information and asked if he would always be a burden on his wife in the aftermath of this acute event. By then one of their sons had arrived and inquired about what types of care his father would likely require. The resident facilitated a conversation focused on their collective observations of limitations, eventually engaging them in a process of problem solving, and exploration of their hopes for his future recovery. At the close of the visit, the resident ensured that Mr. and Mrs. B were given resources regarding therapeutic services, including support groups and respite services for Mrs. B. The referring provider was given recommendations for medication management of symptoms, which had already been shared with the family.

In this case, Psychiatry identified what the family understood about the patient's health and mood and provided education on both topics. The family learned new coping strategies and received referrals to appropriate services both in the hospital and out. Through these interventions, Psychiatry supported Medicine and completed tasks that would have otherwise been the responsibility of the hospitalist and may not have been addressed as thoroughly. Psychiatry's efforts enabled the patient to become active in his own recovery and his family to become participants in discharge planning. Psychiatry helped Medicine transition the patient safely home, reduced the likelihood of readmission, and increased patient–family satisfaction.

Long-Term Care

While the number and variety of housing and residential care options for older adults have evolved to include retirement communities and assisted living facilities, this proliferation has not obviated the need for traditional long-term care facilities. Among the 1.4 million long-term care residents in the United States, 80% have one or more psychiatric diagnoses. Since the 1990s, nursing homes have absorbed increasing numbers of older adults with severe mental illness and serious behavioral problems and, hence, the prevalence of mental illnesses in long-term care populations has increased. Despite the high prevalence of mental disorders in this population, less than one-fifth of nursing home residents with psychiatric diagnoses receive mental health treatment. The recent proliferation of telemedicine and telementoring has increased access to psychiatric and other mental health services for this population. In facilities that do provide mental health services, psychiatrists typically work in one of two models—as consultants or as members of multidisciplinary teams. At present, the consultant model is used more widely, and psychiatrists are most often consulted to address behavioral manifestations associated with adjustment issues, disease and infirmity, and dementia. A survey of geriatric psychiatrists in the United States found that the most common treatment recommendations in long-term care included psychiatric medications followed by changes in the general medical regimen, staff support interventions, medical diagnostic testing, behavioral interventions, staff training, individual or group psychotherapy, and family psychotherapy. These data suggest that geriatric psychiatrists tend not to rely solely on pharmacotherapy, but instead recommend a more diverse range of interventions in accordance with evidence-based practices. In some facilities psychiatry is the discipline responsible for intervening with family issues, especially conflicts between staff and families; in others, disciplines such as social workers, marriage and family therapists, and mental health counselors are available to serve in this role. Since 40% of long-term care residents generally reside with family prior to placement, family involvement after admission is commonplace. Additionally, long-term care placement is a significant life cycle event for older adult families that often triggers the manifestation of a spectrum of family dynamics.

Maria was a 51-year-old Latinx woman of Mexican-American descent and daughter of her 83-year-old father and nursing home resident. Her father, Mr. F., lived in the facility for 6 months following a discharge from the hospital after a car accident that left him with limited function on his left side. Prior to the accident, Mr. F. had lived in the in-law apartment attached to the home where Maria lives with her husband and son and was driving independently within a 5-mile radius of the home. Mr. F. moved into the apartment reluctantly 2 years ago following his wife's death. He did not want to leave his home, his church, or the diner in his neighborhood where he met "the guys" for coffee a couple of times a week. Mr. F. had been well known in the community "in the day" because he owned and operated a popular barbershop for many years. Maria ultimately persuaded him to move so that she could help him more and he would be near family. He continued to grieve the loss of his wife and spent most of his time watching baseball games and old movies and helping his daughter with her garden. His health was stable as Maria supported his medication management of hypertension and high cholesterol, but Maria began to become concerned when he started to lose his appetite, appeared noticeably thinner, and started to become withdrawn. Shortly thereafter Mr. F. was involved in a car accident, was hospitalized and then went to a rehab facility for 2 months. He recovered some function while in rehab but not enough to be able to return home safely.

Mr. F. did not resist moving into a nursing home as he believed he would never be "home" again anyway. After a month or so of adjusting to his recent physical limitations, he began to eat dinner in the dining room. Being an "haz lo que tengas que hacer" ("do what you gotta do") kind of man, the nursing staff and therapists from rehab liked him. He was quiet but friendly and very engaged in therapy. He met other residents on the unit, began to watch baseball with others, and occasionally played cards or checkers when invited. The nursing home staff was pleased with his adjustment to the facility.

Maria struggled with the adjustment. She didn’t understand why he was not getting stronger. She repeatedly advocated for rehab services for her father at least 4 days per week. The social worker overheard Maria commenting to another visitor that “they were giving up on him.” The social worker did her best to validate Maria’s feelings while explaining that her father was receiving as much rehab as he could tolerate. Maria felt better after speaking with the social worker and continued to advocate for more rehab now that “the social worker said that she agreed with her.”

Maria was also displeased with the food her father was served. She was concerned about his cholesterol and displeased that they were not serving him traditional meals like she would have prepared for him. She questioned his dietician about the menu choices he recommended. She advocated for fresh fruits and vegetables and talked about how important gardening had always been to him. She questioned the physician about alternative medicine and use of herbal supplements to reduce his risk of stroke. She decided to back down on that fight and took matters into her own hands by supplementing his diet with lots of green, leafy vegetables from her garden.

At the time of the 6-month family meeting the nurse manager opened by reporting that Mr. F. was doing really well, that he had developed a few friendships on the unit, that his mood had improved, and then declared, “We are all fond of him and I think he is happy here.” Maria became agitated and started to voice other complaints. She asked if his bed could be moved because the sun glare obstructed his view of the TV. The nurse responded politely that she had discussed this with Mr. F. and he said that he preferred it the way it is because he did not wish to give up his view of the outdoors. This confused Maria because she felt that her father no longer needed her to advocate for him.

OPPORTUNITIES FOR INTERVENTION WITH MARIA

Provide Education

- To better understand the physical therapy treatment plan

- To assure her that the meals meet nutritional standards (provide her a sample meal with nutritional breakdown)
- To address her questions about herbal supplements

Improve Communication

- Develop and deliver “team” messages uniformly as a way to reinforce that all team members understand and can explain the plan of care
- Respect the delicate balance between allowing Maria to be “the expert” about her father and assuring her that the staff have relationships with him and are getting to know him also

Use “teach back” or “ask-tell–ask” around topics like his nutrition and therapy

Create Collaborative Team Meeting Formats

- Avoid “Team shares information–Family shares concerns” hierarchy
- Allow Maria an opportunity to add items to the agenda
- Come prepared with answers to questions Maria typically asks

Provide Maria With Opportunities to Be a Partner In Care

- Assure Maria that she maintains a special role in her father’s life
- Encourage her to provide care in alternate ways (e.g., bring in meals her father used to enjoy, buy toiletries, pick out his clothes, decorate the room for holidays)
- Show Maria how her contributions have shaped her father’s plan of care or the way in which care is delivered

Palliative Care Service

Current research demonstrates that patients with advanced, life-threatening illness benefit from care that addresses their psychosocial needs, including loss, grief, quality of life, and suicidal ideation. Though rates of depression are as high as 58% in this population, psychiatric needs often go unrecognized or untreated. Lack of treatment is partially the result of limited availability of psychiatry consultation and clinicians’ perceptions of their insufficient competence to meet the needs of this population.

Patients and families facing terminal illness are often seeking improved quality of life and maximum comfort. Psychiatry can support a patient–family-centered experience that enhances shared decision making about end-of-life decisions, honors patient preferences regarding place of care, and recognizes caregiver fatigue. Families require continued education not only about the disease process, but also about palliative care treatment options. Though palliative care teams are equipped to have these conversations, the dialogue can sometimes come as a surprise to families, and clinicians in psychiatry and medicine can continuously assess the family's readiness for palliative interventions. Additionally, psychiatry is uniquely positioned to help address family conflicts that may arise with respect to different perceptions around end-of-life options and to help families transition from their in-hospital experience to postloss bereavement experience and provide grief counseling.

Ms. P was a 71-year-old Asian American when she presented to the hospital. Widowed for over a decade and suffering from amotivation and anhedonia, she had stopped attending to her own health. She had once enjoyed preparing fresh meals, but she had discontinued this, finding it difficult to cook for herself. She eventually moved in with her daughter and grandson. Her daughter worked two jobs and was a single parent; she found cooking to be taxing and barely found the time to buy groceries. Often, her daughter would return home with fast food or takeout. Ms. P began eating increasingly large amounts of fried foods, sweet snacks, and carbohydrates despite warnings that they were bad for her health. Ms. P suffered from uncontrolled diabetes for several years, episodes of gastroparesis, and chronic kidney disease. Upon hospital admission, she was diagnosed with end-stage kidney disease, and there was a discussion of starting dialysis; alternatively, they noted that without dialysis, Ms. P would likely die. In the interim, palliative care was monitoring the patient's medication management of pain and had started a patient controlled analgesia (PCA). Ms. P was quiet whenever members of the medical team entered her room, as was her daughter; however, her daughter shared her preferences quite openly outside of the hospital room, adamant that her mother should receive dialysis.

Psychiatry was consulted to enhance communication between mother and daughter and to help the team better assess Ms. P's interest in dialysis. Knowing that Ms. P and her daughter remained silent in front of the team, the psychiatrist recommended that a family meeting take place to include psychiatry, medicine, and palliative care. In doing so, the team was able to model (and subsequently encourage) effective communication. The psychiatrist demonstrated the use of open-ended questions, facilitating a conversation that prompted participation from all team members, Ms. P, and her daughter. Ms. P eventually articulated that she was not interested in living a life that required intensive medical care and wanted to be with her husband. Her daughter was tearful but able to verbally accept her mother's choice. Palliative care was then able to provide insight into expectations of the disease process. With this information, the psychiatrist then invited Ms. P to consider other personal preferences and wishes. The psychiatrist supported further dialogue between mother and daughter. At the conclusion of the conversation, Ms. P expressed gratitude that she might die with dignity and was happy to know that she could live her remaining days at home with supportive services and her daughter and grandson nearby.

When Ms. P died a few weeks later, her daughter mailed a letter of thanks to the palliative care team and psychiatrist. She explained the value she perceived in preparing her for the future, avoiding treatment her mother viewed as futile, and improving their communication. She lamented the fact that a family meeting had not occurred sooner in her mother's care, wondering if the last decade of their relationship might have been different. She shared that she previously found her mother's quiet, stoic nature to be one of avoidance rather than resilience and that the family meeting helped her view her mother more positively. She concluded that in giving her mother dignity at the end of her life, the psychiatrist had reduced the family's experience of guilt and grief.

Indications

Family therapy is most commonly used in older adults when the presenting problem is one in which the patient's distress or capacity for problem solving is rooted in a relational context. Family therapy is also indicated when the clinical situation at hand could likely be resolved with brief, solution-focused interventions that are designed to address specific therapeutic goals. Most serious mental health problems of older adults are more successfully addressed when family members are involved in the treatment. Although caution and clinical judgment must be exercised as to the type and timing of family interventions, substantial evidence indicates that psychiatric problems worsen or resolve less completely when conflictual or chaotic family environments are not addressed in the treatment. A major developmental task that families face throughout the life course is finding a balance between supporting individual members to be competent and independent while at the same time remaining connected to and part of the family as a whole. Families are often confronted with this challenge as they encounter life cycle transitions, such as the birth of a child, marriage, retirement, an aging parent, or the loss of a loved one.

Limitations

Older adults are most likely to share psychiatric complaints with their primary care physician, and even then, their report of symptoms is often in the form of somatic concerns. It is, therefore, quite difficult to reach aging families and implement therapeutic interventions without flexibility, integration, and collaboration. Though family therapy is most commonly provided by marriage and family therapists, social workers, and clinical psychologists with specialty training in family psychology, making referrals to family therapists is not always straightforward as requirements for licensure differ by state, and the availability of clinicians is often limited. Reimbursement for family therapy services varies by payer, type of mental health provider, setting, and state. Psychiatrists face similar barriers in the implementation of this work. In addition to complexities regarding access, a major limitation is a pervasive attitude among clinicians that the potential for change in late-life families is negligible.

Contraindications

Family therapy with older adult clients is contraindicated if a patient’s insight or capacity to change is impeded by cognitive impairment, paranoia, or active substance abuse. Conjoint family therapy is typically contraindicated in situations that involve extreme anger on the part of any involved family member or situations in which an assessment has indicated that therapy may increase the likelihood of abuse or other harm. Additionally, it is important to be mindful of the setting in which therapeutic interventions are being applied. For example, in an inpatient medical setting where an episode of care is brief, longstanding transgressions and disagreements are unlikely to be resolved. It is contraindicated to initiate exploration of such work without a plan for follow-up after a hospital discharge or if a referral for outpatient care is not yet established.

Goals of Treatment

Family therapy interventions are used to reduce clinical symptoms that impact the individual and the family system. As noted, such interventions can be utilized to improve function by effectively changing the family's structure, patterns of interaction, problem-solving abilities, capacity for empathy and understanding, communication skills, and sometimes the meaning that a family ascribes to a certain event or situation. In addition, addressing a family's response to medical illness, death and dying, and the aging process is critical. The cases presented in this chapter provide examples of the multiple layers of family dynamics that accompany the transitions older adult families often confront.

ETHICAL ISSUES

Providing treatment to older adult families at critical times of transition is embedded within layers of complexities. The settings in which the care is provided often introduce additional ethical considerations that may interfere with the provision of optimal patient- and family-centered care. Some ethical issues that clinicians are likely to encounter are discussed here.

End-of-Life Care

Patients, families, and care teams encounter difficult life-and-death decisions, which encompass medical decision making, comfort management, and emotional and spiritual well-being. Though formal documents and legal statutes in the United States emphasize the importance of individual autonomy and independent decision making, research suggests that older adults want family members involved in end-of-life decisions. Those suffering from a chronic and terminal illness may experience cognitive changes that impede their ability to make decisions independently and benefit from familial support. Despite this fact, the research indicates that older adults and their children often disagree on key factors about the end of life. Clinicians can support patients and families by facilitating open dialogue about end-of-life preferences, especially before patients lose the capacity to share their wishes.

Clinicians further assist families in making decisions collectively by addressing the family's relational dynamics and life cycle considerations. Such conversations may occur rapidly in acute medical situations that require immediate decision making or more slowly at the outset of a chronic illness. In some instances, family members do not support their loved one's preferences regarding the use of life-sustaining measures. Such scenarios may require the development or enhancement of families' natural problem-solving abilities, modeling of adaptive communication, or grief work. In such situations, clinicians are challenged to balance the patient's needs while acknowledging the larger family experience and preferences.

Capacity and Decision Making

Decisional capacity refers to a person's ability to make their own decisions in a variety of contexts, including those related to health care. The issue of consent or refusal of treatment regularly arises when working with older adults, particularly in the inpatient setting. Some have argued that the medical conditions older adults face can contribute to feelings of helplessness, thus rendering them more open to the undue influence of others. Though clinical methods are available to assist with assessing capacity, this determination is made amidst multiple contextual factors. Psychiatrists are thoroughly trained to assess capacity, but it is important to not only determine the patient's ability to understand and reason but also to ascertain a sense of the patient's values prior to the onset of illness. Such evaluations and subsequent information sharing with the patient attempt to honor patient autonomy and appropriate family inclusion. It is important to understand shared versus conflicting values held by the patient and family and the risk of conflict and potential coercion when values and wishes do not align. Further, if a patient is deemed "incompetent," clinicians also consider whether the surrogate decision maker is acting with the patient's values and best interests in mind.

Cultural Considerations

Each generation of older adults gives rise to a unique set of values, beliefs, and family dynamics. These factors impact how older adults and families interact with the healthcare system and can play an important role in treatment decisions and outcomes. As increasing numbers of Baby Boomers reach the age of 65, it is important for clinicians to recognize the different social and demographic characteristics that define this unique cohort. Individuals in this group tend to be more educated than their predecessors, have more access to health care information, hold higher and more specific expectations of the health care system, and have a tendency to challenge authority. Baby Boomers are more open to receiving mental health services than previous generations. Despite these overarching themes, Baby Boomers comprise a heterogeneous group. Thus careful evaluation and treatment planning are fundamental to providing care that honors and respects the cultural and generational considerations of patients and their families.

In addition to generational considerations, U.S. Census data from 2019 indicate that nearly one-quarter of the over-65 population is comprised of members of racial or ethnic minority populations. There is a need for practice guidelines addressing the feasibility and acceptability of family therapy approaches across these populations.

Elder Abuse, Neglect, and Exploitation

Elder mistreatment, including abuse and neglect, is a public health problem of significant concern. Estimates indicate that one in 10 older adults in the United States alone are victims of abuse or neglect. Community-based studies indicate that one in six individuals over the age of 65 experienced abuse in the prior year, and over half lived with the perpetrator of abuse. Older adults who are cognitively or functionally impaired are at higher risk for abuse, and some who experience severe disability are unable to report maltreatment. Elder abuse is one of the strongest predictors of long-term care placement. Advanced age, female gender, being in a spousal relationship, African-American race, living with others, physical and economic dependency on caregivers, isolation, intergenerational conflict, substance misuse, and mental illness have all been associated with increased risk of abuse. Additionally, published reports suggest that family members who perceive a high level of caregiver burden, have a history of their own mental health needs, or have a history of substance misuse, may be more likely to engage in abusive behaviors, particularly when seeking compliance from the one needing care.

Clinicians must be alert to the needs of patients and their caregivers. It is helpful to look for signs of abuse or neglect, including repeated, unexplained bruises or injuries, malnutrition, fearfulness around particular family members, or, in the case of those who are being financially exploited, a discrepancy between their ability to pay for personal commodities and their reported level of income. Clinicians can reduce the risk of abuse by conducting thorough assessments of caregiver burnout and by attending to the caregivers' experience of an aging relative. Family therapy is recommended to mediate conflicts that might give rise to mistreatment, but more research is needed to understand the treatment techniques that are most effective.

The majority of states now have mandatory reporting laws for elder abuse, as well as state or county-funded protective service programs for older adults who have been abused or are at risk. Practitioners are responsible for knowing state reporting laws. Although estimates indicate that one-third of actual cases of child abuse are reported, some studies estimate that only 1 in 24 cases of elder abuse is reported. Older adults are often reluctant to disclose the problem for fear of retaliation from an abusive family member. Further limitations to the frequency of reporting are thought to be related to the professional’s fear of offending the patient or family or placing the patient at greater risk for harm.

RESEARCH AND EVALUATION

Despite the growing knowledge base on family systems and life cycle approaches to the treatment of older adults, evidence of the utility of these methods remains sparse. A recent examination of therapeutic outcomes across the lifespan found that while older adults differed from younger adults on key therapeutic issues, age was not significantly related to the amount of change observed over time across all individual and relational measures. In contrast, there are numerous studies on the effectiveness of psychoeducational interventions and cognitive-behavioral psychotherapies that are focused on family caregivers of older adults. Many of the most promising advances in the field are rooted in ecosystemic interventions that are delivered outside of the traditional healthcare practitioner’s office. These interventions have been demonstrated to have positive effects on such outcomes as caregiver burden, depression, subjective well-being, knowledge and skills, and physical health, as well as on the level of symptoms expressed by the older adult receiving care. At present, research on caregiving, social isolation, elder abuse, and end-of-life care are the most fertile areas for investigations of family therapy approaches.

55.4k Group Therapy

Kenneth M. Schwartz, M.D., F.R.C.P.C., Ingrid Söchting, Ph.D., R.Psych., C.G.P., Shayne Vitemb, M.A., L.M.F.T., C.G.P., and Alvin Keng, M.D., F.R.C.P.C.

Relevant models of new applications of group therapy are emerging steadily to meet the increasing needs of older adults with complex medical and mental health issues, although evaluation and research have yet to keep pace with these clinical developments. Foci of intervention include the aging-related losses of interpersonal, emotional, social, physical, and cognitive capacities. The group therapies provide demonstrably effective treatment achieved through improving social support and engagement while enhancing individual patient and family member coping capacities and skills. Group therapy is provided in ambulatory, hospital, and institutional settings and ideally should also be available in community and primary care settings. Online delivery of group therapy also deserves special mention, with unique considerations around access, privacy, and equivalence to in-person delivery. In all instances, the group leader's belief in and commitment to the continued potential for growth and change in later life is of overarching importance and is at the heart of clinical effectiveness in groups for older adults.

HISTORY

The roots of group therapy can be traced back to the work of social workers in a variety of settings for seniors, including homes for the aged, community centers, and mental health institutions in the earlier part of the 20th century. Group interventions combined activity and psychosocial treatments, emphasizing didactic instruction, inspiration, and social support, often referred to as a therapeutic milieu. In the following decades, interest in psychodynamic group approaches with older adults gained prominence as Maurice Linden, an American psychiatrist and pioneering group therapist, wrote a series of transformative articles on the topic. His careful observations led to the conviction that group therapy provided institutionalized patients with psychotic and various degrees of cognitive decline opportunities for resocialization, happiness, and some measure of self-sufficiency. Linden's perceptions have stood the test of time. The group approach was well tolerated by patients, satisfying to staff, and economical. Group therapy has since broadened its reach with the provision of treatment in acute care settings, day hospitals, ambulatory, and community settings. Accompanying this has been a shift in the emphasis from the powerful and caring leader to interpersonal models emphasizing the importance of relationships between group members in healing and change. Also, not only are psychotherapeutic interventions routinely integrated with pharmacotherapy, but the recognition of the limits of singular models has encouraged integration within group psychotherapy itself, synthesizing the benefits of cognitive-behavioral, dynamic, and developmental models. As is common in the field of group therapy, practitioners continue to respond to emerging clinical needs with diverse populations with a renewed emphasis on creating evidence-based models of intervention that are applied and then evaluated.

Current models include (1) verbal groups for the cognitively intact, which include groups for burdened caregivers; (2) verbal groups for the cognitively impaired, including cognitive stimulation, resocialization, remoralization, and reality orientation groups; (3) verbal virtual groups; (4) activity- and creativity-centered groups, including dance movement, drama, music, art, and poetry groups; (5) a variety of time-limited homogeneous groups addressing issues such as retirement, depression, anxiety, bereavement, loneliness, and medical illness (i.e., HIV/AIDS, chronic disease, pain); and (6) self-help and advocacy groups.

THEORETICAL ISSUES

Older adult individuals cover a large range, from baby boomers to centenarians, with an increasingly diverse range of diagnoses, abilities, and racial, gender, cultural, and religious backgrounds. The need for more effective psychological treatments will become more, not less important, as the increasingly aging population becomes more psychologically sophisticated, having utilized psychotherapy at earlier stages of life.

The themes encountered in older adult groups include reactions to loss, both developmental and traumatic, and to decline, with the resultant discontinuity with a prior, more valued sense of self. Consequently, themes revolve around issues of maintaining dignity, increased need for help and dependency, social isolation and loneliness, changing roles and/or conflictual relationships with adult children, mourning of losses of spouse and/or health, and existential struggles with retaining a sense of meaning and purpose. Certain ageist and stereotypical attitudes of society and some group leaders regarding, for example, late-life sexuality and intimacy contribute to the neglect of these subjects being rarely discussed in older adult groups.

Depression among older adults is a major public health concern with prevalence estimates for severe depression up to 9% and for milder up to 37%. Depression is often comorbid with other mental or medical issues, chronic, and with high health care costs for both the individual and society. Loneliness and the lack of social support are profound risk factors for depression. Group therapy provides opportunities to grieve losses and to re-engage with interests and relationships. It provides real relatedness alongside the acquisition of skills needed to generate continuing social integration beyond treatment. Because the experience of relatedness generated in the group is the result of the members' own actions, feelings of dependence may be reduced and feelings of personal competence may be increased. Enhanced social support produces a primary effect of improved well-being and a secondary, stress-buffering effect, which is particularly important for older adults. The importance of these supports and networks was highlighted during the COVID-19 pandemic. Higher levels of social support are associated with improved treatment outcomes for depression.

Often, group members experience shame at having lost their prior sense of self, viewing the current "incompetent" mental and/or physical replacement to which they must adjust as "bad" or "defective." In groups, they can be assisted to learn that their presumed defect is merely human and that other members also struggle with similar thoughts and feelings. The sharing of painful and deeply personal concerns can reduce the shame and stigmatization that isolate the individual. Through the therapeutic mechanism of altruism, members help one another, simultaneously raising self-esteem for both the receiver and provider of support. Realistic hope can similarly be nurtured countering feelings of demoralization and despair. Hope is malleable and can evolve with support to focus on new wishes and aspirations despite the undeniable decline, loss, and limited time. The vignette of Mr. G illustrates a group process leading to a more hopeful and renewed sense of self.

Mr. G, an 80-year-old man voiced displeasure at others in wheelchairs even though he himself needed one. He spoke with disdain about initially needing a cane, then a walker, and finally a wheelchair “because I do not want others to feel sorry or look down on me.” A second group member agreed while adding that she had only started using a wheelchair recently “against my wishes.” A third member, also in a wheelchair asked “Is it possible to retain one’s independence and pride while in a wheelchair living in a nursing home”? She then answered her own question stating “I do whatever I can for myself and I have ways to help others.” Other members in the group, both with and without wheelchairs, shared their own struggles in both seeking and accepting help, with other health issues as well, such as the loss of hearing or vision. Most acknowledged they were better at giving than receiving because they were raised that way. After more discussion, all the members, including Mr. G., agreed that accepting help when needed was a sign of strength and something that they wished at this later stage of life to learn to accept without shame or feeling like a burden to others.

Combined pharmacotherapy and psychotherapy are progressively employed in the acute, maintenance, and continuation phases of treatment. Combining drug and psychosocial therapies demands that attention be paid to the meaning each treatment has to the individual while being cognizant of the risks of devaluing one modality over the other. For example, a medication group where participants are encouraged to discuss their shame and fears associated with taking antidepressant medications can lead to better medication compliance and thus improvement in symptoms of depression. Group members realize through their interactions that despite negative feelings associated with taking medication, they are better able to accept the use of medication.

A metatheoretical synthesis of dynamic and developmental approaches along with cognitive-behavioral approaches into a seamless whole emerges from the recognition that effective psychotherapy is facilitated by understanding of the individual's private, subjective experience residing beneath more manifest interpersonal behavior, bridging emotional insight of oneself and others with skill acquisition. In all instances, the overarching goal is to increase each group member's sense of self-efficacy and dignity. Restoring a sense of personal effectiveness and the recognition of cause and effect in one's life is essential. This integrative model emphasizes the individual's sense of agency, as opposed to viewing oneself as a victim, of their own relational world. It combines interpersonal feedback within the here-and-now of the group and the processing of extragroup events and assigned homework, adding intensity and immediacy that enlivens cognitive and behavioral approaches. Behavioral activation and skills training build atop this. Allied with these more traditional and recent approaches are mindfulness-based cognitive therapy (MBCT) groups and dialectical behavior therapy (DBT) aimed at increasing reflective capacity, reducing reactivity, and enhancing skills in regulating negative emotions. Adapted for older adults, these approaches also focus on teaching skills to enhance openness to new experiences and in creating meaning over the course of life.

TECHNICAL INTERVENTIONS AND GROUP APPROACHES

Technical expertise in the application of group therapies is surpassed in importance only by the therapist's posture of respect, hopefulness, genuine warmth, and empathy. Study after study has reiterated the findings that effective group therapy is predicated upon a strong sense of group cohesion and the leader's capacity for both receptive (understanding) and expressive (communicative) empathy. Beyond the relationship between member and leader, successful treatment hinges on the establishment of group cohesion. Modifications of therapy approaches are sometimes necessary for group work with older adults in order to achieve and maintain cohesion. These include flexible use of protocols, the adaptation of cognitive restructuring techniques, additional supportive techniques, and practical arrangements for problems in hearing, vision, mobility, and other disabilities. Nonetheless, cohesion may be difficult to achieve with demoralized, withdrawn, and self- or other-devaluing patients. The group therapist, or therapists in groups with cofacilitation, need to be mindful that cohesion emerges both from the emotional bond shared by group members and the group's effectiveness with its designated tasks. Therapist interventions follow from the understanding of the tasks and goals of the therapy. The rationale for the group and the therapist's intervention should be transparent and clear. Cotherapy may be useful in providing an appropriate level of focus and activation, continuity during therapist absences, and the added opportunity to address countertransferential reactions through cotherapy discussion and the coconstructed space for thinking. Within institutional settings, cotherapy also facilitates the transmission of information between the group and other institutional care providers to ensure maximum treatment integration and reduce institutional resistance to group interventions.

Older adult groups focus on helping members cope with medical, psychological, mental health, and societal challenges associated with aging. Emotion-based coping in verbal groups helps reduce or manage the intensity of the emotional distress through the sharing of thoughts and feelings. Too often these feelings end up being expressed through somatization or the use of drugs, alcohol, or other less healthy ways. Problem-based coping is emphasized in situations in which something constructive needs to be done. Based on problem-solving therapy, a derivative of cognitive-behavioral principles, it is a more practical approach to help address problems by systematically examining and finding external solutions to problems without depth exploration. Existential-based coping is an opportunity to make use of the older adult's awareness of the limits imposed by aging and decline but also of the revitalization that can occur by focusing less on regrets over things undone or unsaid and more on living in the present before time runs out. The overarching goal of the therapist is to increase each group member's sense of self-efficacy. Restoring a sense of personal effectiveness and the recognition of cause and effect in an older adult's life is essential. The integrative model emphasizes the individual’s sense of agency, as opposed to viewing oneself as a victim, of their own relational world. It combines interpersonal feedback within the here-and-now of the group and the processing of extragroup events.

Attention must be paid to the maintenance of group norms and group integrity, which may be challenged by patient or institutional resistance. Patient resistance may be difficult to discern and can be interwoven with the severity of illness and comorbid illness, as well as on practical issues such as reliance on others for transportation to and from the group. In institutional settings, a positive alliance between the group therapist and administration is essential. Group therapy inevitably reflects the culture and norms of the larger milieu in which it is embedded. The principle of isomorphy notes that important concerns, values, and fears are transmitted throughout the institutional system and gain expression at every level, from patient to leader to group to ward to institution. Hence, an opportunity for dialogue and interchange between all the stakeholders in the treatment environment is invaluable while striving to ensure appropriate privacy and confidentiality within the circle of care.

A key aspect of this is to ensure that group sessions in institutional settings are scheduled in an accessible location without conflict with other scheduled activities. Active outreach including the arrangement of portering may be required to promote regular attendance. Groups for the older adults may often be held at midday in ambulatory settings and may be contiguous with lunch, to encourage opportunities for social interaction around mealtime. In institutional settings and day hospital programs, the treatment frame is also affected by the fact that group members will often have involvement with one another outside of the group. Opportunities for engagement and interaction outside of the group can be employed as part of the prescription of behavioral interventions and to facilitate homework. In all instances, a group norm should be established that protects the confidentiality of the group members and encompasses extragroup contact within the treatment frame.

Therapy groups generally consist of 6 to 10 patients, but activity groups or groups for depressed or frail populations may be larger and benefit from the increased energy in the room. Duration of sessions is shaped by members' capacities and may vary from 30 minutes daily for cognitively impaired patients to 90 minutes weekly for more cognitively intact patients. Many group formats are ongoing, but the majority of cognitive-behavioral groups and groups for burdened caregivers are closed and time-limited, lasting from 6 to 20 sessions. The limits of briefer treatments are being recognized, and treatments are often extended to include follow-up sessions that meet at a reduced frequency, but over a longer period of time, to extend treatment into maintenance and continuation phases. It is not uncommon in some settings to see members attend a monthly maintenance phase meeting for many years or for group participants to continue to meet informally after the group sessions end.

Group models are also developing outside of traditional venues. The COVID-19 pandemic has also impacted group therapists who have had to move groups from a circle of chairs in offices to online virtual platforms where members view frames of each other, from the circle to the square! Learning new technology and attending to new privacy concerns has been especially challenging for older therapists. A similar challenge exists for older adults to not withdraw into a "gero-pause" which is an avoidance of pursuing new interests or skills because it is too hard or complicated.

The ideal treatment setting will offer an array of group therapy options, phasing and tailoring interventions to patient requirements with graded levels of intensity and depth. The therapy should be experienced as a self-esteem–enhancing and sustaining experience and a nonfailure experience for each member. Therapist activity must focus on promoting group interaction in ways that maintains the dignity of participants. The therapist should achieve a balance between support and expression and may need to intervene with active prompting, reinforcement, reframing, and modulation of emotional intensity, emphasizing the invitation for what is desired rather than the rebuke for what is not. An important therapeutic task is the empathic confrontation of projective defenses and resistance while at the same time showing empathy for a group member's wish to protect themselves during an increased time of stress. That may result in disengagement that isolates individuals and undermines group cohesion. The therapist may need to be quite active in reinforcing progroup or procohesion exchanges, bolstering patient feelings of worth and belonging. It is essential not to permit depressive affect to overwhelm the group as depressed older adults are particularly prone to the effect of demoralization.

Below we review various group approaches and techniques including cognitive-behavioral therapy (CBT), existential, life review, activity, caregivers, and cognitive impairment. While there are other approaches, these are the major ones for older adult groups.

Cognitive-Behavioral

CBT emphasizes conscious cognition and new learning. The CBT model lends itself easily to a group setting for older adults. Cognitive techniques can help patients realize long-standing patterns of unhelpful (usually overly self-critical) thinking patterns that reinforce inaccurate and self-sabotaging beliefs about the self, others, and one's environment. In the above case of Mr. G, he erroneously believed that "the world" pitied him because of his confinement to a chair. Behavioral approaches focus on remediating the patient's reduction of environmental or social reinforcement often a result of their withdrawal, diminished interpersonal interactions, and thus "rustier" skills, but also an increase in legitimate adverse life events such as losing people to death and losing one's independence and abilities.

The cognitive behavioral approach emphasizes the teaching of skills with a consistent focus on patients assuming responsibility for practicing new behaviors including new thoughts, crediting themselves for improvements, and stimulating a sense of self-efficacy and mastery. Larger problems are deconstructed into smaller, more manageable components, as realistic goals are set, also referred to as the "chunking" approach. Behavioral techniques include goal-setting, but also other interventions such as modeling, role-play, psychoeducation, behavioral exposure to anxiety stimuli, and the review of homework with the provision of feedback about each group member's efforts in using prescribed skills to re-engage with pleasurable experiences or approaching previously feared situations.

Therapeutic strategies also include education about common "thinking traps" people of all ages are prone to. These include *catastrophizing* (e.g., "It will be terrible if I end up in a care home"), *mind-reading* (e.g., "They clearly feel pity for me"), and *black-and-white* thinking (e.g., "If I can't sing the way I used to why bother at all."). Patients are helped to examine evidence for and against their beliefs and to find alternative explanations that are more fair, accurate, and for sure helpful. The example of Mr. G illustrates a cognitive shift to a belief of still being able to contribute and enjoy mental stimulation despite physical mobility limitations. It is noteworthy that this shift was brought about by help from fellow group members who presented evidence countering Mr. G's previously held, more rigid beliefs. It is imperative that skilled group facilitators activate the entire "group brain" during the cognitive restructuring process and avoid relying on themselves to persuade a patient to "think positively."

In another example of Mrs. A from a CBT group, we see how the group can gently challenge a member to take a step out of their comfort zone.

In a day hospital for depression, Mrs. A, a 78-year-old widow, commented upon entry to the group that she was depressed and that “the group will not help me.” Other members of the group suggested a thought-challenging record could improve Mrs. A’s mood. Group members then assisted Mrs. A in finding evidence that did not support her belief of “being beyond help.” In a later session focused on creating personal action plans, Mrs. A observed she had withdrawn from her friends, was not returning phone calls, and was declining offers to socialize. Encouraged by the other group members, she decided on the action plan of returning a phone call to a friend. In the next session, she reported that she was able to complete the action plan of phoning the friend. Her friend was happy to hear from her and Mrs. A noticed her mood improved as a result. Having achieved this success and feeling the improved sense of well-being from having had a meaningful connection with a friend, Mrs. A decided that she would call a friend several times a week. Most importantly, she decided to stay with the group which contrary to her initial belief now seemed helpful to her.

CBT groups are quite structured, usually following a protocol with preset session content, check-in, and check-out, homework review, new learning, assignment of new homework, and discussion of anticipated obstructions to completion of the homework. It does require a baseline of cognitive capacity but can easily accommodate normal cognitive decline and early stages of dementia. Group therapists must respect the impact of slower cognitive processing and ensure adequate pacing, appropriate repetition, and reinforcement of new learning. The group setting is ideal for this model, linking together mutual support, positive modeling between group members, and the collaborative challenging of common cognitive and behavioral contributions to distress and depression. Group therapy outcome research indicates that the group format is just as effective as individual CBT, if not superior in some cases.

Although CBT groups are effective across the lifespan, an important drawback is the lack of active use of the group process. Finding ways to augment CBT by capitalizing on the valuable group process presents a challenge for most group CBT therapists. Promising efforts to integrate both a structured and a process approach have been made. A program at an outpatient clinic at a hospital in Western Canada developed an intensive, time-limited group therapy program for patients aged 65 and above. A CBT and an interpersonal therapy, IPT, group are each held on two consecutive days (IPT on Monday and CBT on Tuesday) over a 16-week period. Each group lasts for 90 minutes. Patients thus receive 3 hours of weekly group therapy for 16 weeks. The groups are closed, and size ranges between 7 and 10 members. Standard CBT interventions as described above are integrated with an IPT protocol adapted for a group format.

IPT is derived from attachment theory and recognizes that interpersonal function is a critical component of psychological adjustment and well-being. Group IPT therapists use stage-appropriate interventions and lead the group through the initial engagement stage, to differentiation, to work, and to termination. Similar to individual IPT, group IPT helps patients gain a sense of mastery and restore a sense of social belonging and meaning in life, with the emphasis primarily on current interpersonal relationships. Focusing on the elaboration of affect and self-disclosure is useful in gaining an understanding of the individual’s internal world, and the process of reminiscing (life review) may further flesh this out. The facilitators do not preplan thematic discussions or set agendas, but they help the group organize emerging discussions by identifying themes and may also encourage the group to carry over or revisit a particular topic. For example, goals set in the CBT group may be addressed in the IPT group from perspective of lacking motivation, and missing one’s spouse to do things with.

Existential

Contrary to the common reputation of Existentialism as a gloomy way of thinking, obsessed with death and dread, existential thinking can be seen as a dynamic, invigorating approach that encompasses a range of states of being in the world—from alienation and isolation to connectedness and transcendence. These aspects of existential thought can deepen the work of group therapists working with older adults and can be integrated into or inspire a variety of types of treatment in group therapy.

Existential psychology as well as existential philosophy can be said to share their early roots in a kind of response to Descartes' famous statement, "I think, therefore, I am." This statement, revolutionary in its time, helped a chaotic Europe emerge from a world of violence into a realm of rationality and civilization. But over time, the full context of Descartes' statement was lost, placing rationality in center stage, while leaving the "I am" part of this statement neglected. Existentialists placed the emphasis on the "I am" part, insisting on examining existence or being, not just thinking, as an opening into a discussion of human existence.

Group therapy for older adults has the unique capability of providing its members with an opportunity to examine what it means "to be," as well as what it's like to "be in the world." Group members can explore such questions as, what do I make of the world I am now living in, and what does it mean to "be" in this world? Is there a place for me? Do I have a contribution to make? Can there still be passion in life, and are new friendships possible? What about the past?

Some of the more common understandings of existentialism focus on death awareness and the finiteness of life as a path to the appreciation of life in the present. With older adults, there is less of a need—perhaps no need–to heighten one's awareness of death—they know it all too well. Group members are likely to have already experienced profound loss and, due to their age, know that they have more years behind than ahead of them. Many have been treated for serious illnesses or have loved ones who suffer from very specific life-threatening problems such as cancer or heart disease. For them, awareness of life's finiteness may be a source of very real and present pain. With this in mind, processing around issues of death need not be emphasized, nor should they be feared or avoided.

The focus of existential group therapy with older adults can focus on such existential concepts as isolation, everyday life, existential anxiety, and life's meaning as identified by psychological thinkers such as Irv Yalom and Rollo May. Making good use of the awareness of the finiteness of time in the group, such as the 90-minute session as a metaphor for life with its beginnings and endings is of great value. Members may seek support in repairing damaged relationships with adult children, or reframing what is meaningful to them, as well as forming new connections that bridge isolation in the here and now of the group therapy experience. Ideally, the group can be a haven for an "I-Thou" experience as inspired by Martin Buber, in which one is connected to another being in a very genuine way, with less pressure from external constraints including social status and pressure to be "nice." When bringing existential influences into one's group work, it is important that the concepts not be rigidly or dogmatically imposed, since its essence is an honoring of the authentic experience of individuals and the freedom and responsibility that entails.

Life-Review

Life review and reminiscing techniques employ the naturally occurring process of patients' recollections and reviews of their lives. It can serve as a vehicle for making meaning of one's life, viewing it as valuable and of consequence. Furthermore, the life review approach can facilitate the resolution of old conflicts and acceptance of losses and the unchangeable facts of one's life. When used in a group format, it also creates a sense of social identification among group members. Reminiscing can be used as the main treatment focus or to stimulate cohesion in beginning groups as an introductory exercise. Reminiscing can be spontaneous or prescribed in a series of sessions, following a chronologic life course sequence. Either mile stoning, which emphasizes only positive events, can be utilized, or the review process can be comprehensive and autobiographical, providing an opportunity for mourning, conflict resolution, and acceptance. Encouraging a focus on the past is not without risk. Facilitating the group members' return to dialogue within the here-and-now of the group, eliciting feedback and interaction, ensures that morbid self-absorption, preoccupation with painful memories or regrets, and guilt do not exacerbate the individual’s withdrawal from the group or adherence to the past as a way of avoiding engagement with the present.

Activity and Creativity

Activity- and creativity-centered groups (e.g., dance, movement, pottery, music, or drama) encourage social engagement through shared participation in a pleasurable activity that may rekindle a connection with the previous sense of self through the use of the creative process. Group activities elicit feelings of pleasure and mastery, challenge self-denigrating and constrictive distortions that individuals may have about themselves, and counter the trend toward homogenization. Although the focus in the group is on physical activity, integrating a psychodynamic appreciation of the meaning of the activity groups amplifies the use of a physical activity to promote social interchange. This has been demonstrated to assist in role transition, acceptance of loss in body function, and integration of new goals, interests, and meaning in life.

Caregivers

Groups for caregivers are used widely in response to the increasing number of frail or cognitively impaired individuals being cared for in the community by their families. Increasing longevity is a challenge for both society and family members, generally unprepared with little knowledge and few skills to deal with their loved one’s physical and especially cognitive decline associated with dementia. These caregivers are often highly stressed, isolated, overwhelmed, and have an increased risk of psychological, physical, and financial problems, yet they remain the key resource to the implementation of any interventions for the identified patient. Groups may provide an opportunity for working through feelings of loss and abandonment, as well as anger at the burdens imposed on the caregiver. Attention to the process of the giving and receiving of mutual care within the actual groups provides a direct opportunity to address self-management and self-care issues. Education, social support, and skills training may all be integrated into these groups. Using a simulation of emotionally challenging caregiver scenarios is also being applied to good effect in facilitating the direct application of specific and relevant coping skills. Group therapy interventions for caregivers work best when they integrate a variety of techniques that are structured and intense; require the active involvement of caregivers, include education, support, and respite; promote knowledge transfers, skill building, and competency; and are combined with individual support.

Cognitive Impairment

Growing attention to individuals with mild cognitive impairment is evident in groups that provide psychoeducation, support, and coping strategies for couples with the objective of reducing anxiety, aligning expectations, and jointly coping while reducing marital stress. Groups for cognitively impaired patients focus on patient engagement, with the structure of the group activity employing multiple modes of cognitive stimulation. Interpersonal and group processes are generally not addressed. These groups employ a broad range of sensory and cognitive stimuli to activate and engage patients, with consistent reinforcement and validation provided by the leader(s). The therapist should be guided by the principle of conferring meaning to every patient's communication rather than dismissing these expressions as irrelevant. Cognitive exercises, activities, word games, life reviews, discussions, participation in arts and crafts, pleasant aromas, music; baking; guided imagery; relaxation; and physical exercise are components of these groups. What links all such groups is the moment-to-moment focus on esteem-enhancing patient engagement with the world around them. Groups of 6 to 10 participants work well. The group should be small enough that each member actively participates. Future growth in these approaches is likely, reflecting the growing role and positive effects of nonpharmacologic interventions for dementia recommended in contemporary practice guidelines.

CLINICAL ISSUES

Countertransference Challenges

The depth of the despair associated with some older adults' struggles with their living situations in the community or long-term care settings can be occasionally difficult to endure for the therapist and lead to withdrawal from working with these populations. Patients and therapists must understand that demoralization is a state—it is a specific emotional reaction and not an obligatory trait of aging. While recognizing age-related limitations of time and energy, the belief that an older adult's life will be one of unhappiness and despair can be challenged, often through the countervailing experience in the here and now of the group, and successful aging and improved mood can be resumed. Identification with a member's position of hopelessness loses the therapeutic perspective. While instilling or reinforcing hope is essential, therapists must be careful in a wish to avoid inflicting pain on members or themselves by offering unrealistic hope, which may indicate discomfort in hearing about the struggles of certain members. When this occurs, members will experience their emotional pain as being dismissed and not being shared in the group. Realistic expectations help therapists guard against such negative countertransference associated with profound difficulties with hopelessness, self-criticism, and beliefs about one's competence. Fortunately, there are enough rewards, including older members offering an explicit appreciation of the therapist's understanding and acceptance of who they were and still are, to make work with this increasing and still underserviced population so worthwhile.

Another critical issue involves age discrepancy, as the therapists are almost always younger than the group members. Working with older adults can have an impact on therapists who are younger or perceived as younger (e.g., "you could be my grandchild") than their patients. This consideration is an important aspect of the provision of group therapy to older adults. The countertransference experienced by younger therapists warrants full and fair exploration in supervision. Prior to commencing group therapy with older adults, younger therapists should be prompted and encouraged to explore their motivations, apprehensions, and preconceived notions of the upcoming work. During the course of therapy, strong reactions may develop among younger therapists. For example, patients may be reminded of parental or authority figures from their past or present. Conversely, patients may also be experienced as benign, frail “grannies” who need to be “taken care of” based on the therapists’ experience and memories with their own grandparents. Age in countertransference is also fluid, and such roles are reversed. Supervision around these topics, therefore, should not be presumptuous and should be provided on an ongoing basis. Younger therapists are also more likely to engage with this modality for the first time as a trainee. Regular supervision allows for addressing their unique educational and professional growth needs and will ensure future generations can continue this work with aptitude and confidence free of therapy-interfering projections.

Indications and Contraindications for Group Participation

The choice of a group modality for older adults may take into consideration both practical issues, such as the availability of various group types, along with affordable and convenient transportation, and patient issues, such as the type and extent of psychiatric illness and/or cognitive impairment.

Group therapy may be used as an adjunct to pharmacotherapy, or individual treatment, or as an independent treatment. With respect to selection criteria, structured groups, especially those that are more homogeneous in terms of membership, ego functioning, and cognitive capacities and not age alone, are more effective than unstructured groups. There is a potential for poorer treatment outcomes in groups that lack either focus or appreciation for the potential to amplify depression by intensifying affects related to illness and death beyond some members’ capacity. As with all treatments, therapeutic success is enhanced by the linking of patient goals and abilities to the tasks and techniques of the treatment. Mixing cognitively impaired and intact patients together is likely to jeopardize cohesion and group effectiveness by generating a wish among members to disidentify and withdraw from the more impaired participants.

Although pregroup preparation has not been extensively researched with older adults, the evidence for its usefulness in other patient populations is quite substantial. Pretherapy preparation outlining the group treatment's goals and methods demystifies an otherwise anxiety-provoking situation, normalizes and destigmatizes treatment, helps to establish a therapeutic alliance, and sets group norms regarding regular attendance, confidentiality, and extragroup socialization. This process may increase group therapy tenure and task adherence and foster patient hopefulness. Role-play or simulations may be utilized to induct the patient into the therapy role.

A written summary of the group therapy logistics, norms, tasks, and expectations may be useful to supplement the preparation interview. Pregroup preparation should also explore treatment resistance. Identification of ego-syntonic character difficulties, in particular narcissistic pathology or interpersonally alienating behaviors may be useful in containing behaviors that can result in early peer rejection from the group.

Dropout rates in group therapy, in general, range between 10% and 50% in younger adults and are likely the same with older adults. The likelihood of premature termination from treatment increases with increasing severity of depression, comorbid physical illness, and comorbid characterologic difficulties of devaluation and externalization.

Burdened caregivers are a notably vulnerable group. Limits in health care resources coupled with an aging population have resulted in the common situation of caregivers routinely providing at home the kind of care that in a previous generation was provided by professionals. Caregiver stress emerges from strain around safety, managing patient problematic behavior, self-care, social support, and personal emotional well-being. Caring for the cognitively impaired individual generates greater psychological strain and burden than caring for the medically ill. Family caregivers are often disproportionately vulnerable to both psychological and medical illness.

Contraindications

In general, individuals who require acute and active management because they are in crisis, suicidal, actively abusing substances, or acutely psychotic, do not do well in general groups. Severe cognitive or sensory impairment or medical illness that obstructs the individual's engagement with the group enterprise may also require exclusion from group therapy. Some contraindications are relative and can be remedied by employing groups that are homogeneous for that condition. A program that has very few dropouts or therapy failures likely has set the bar for entry too high and may be missing opportunities to treat some patients who could benefit.

Goals

Notwithstanding the range of group formats described, consensus exists regarding realistic goals of treatment. Although obviously shaped by particular patient needs, in general, the goals of treatment include reduction of symptomatic disturbance; reduction of isolation; restoration of interpersonal skills and engagement within a social network; correction of psychological distortions and cognitive beliefs; restoration of self-esteem; improved cognitive function; acquisition of problem-solving and coping skills; grieving and adaptation to loss; and realistic acceptance of one's needs and limitations with effective use of available resources. In institutional settings, group therapy may provide a forum to deal with the imposed inhibition of personal autonomy associated with routine, regulation, and restricted opportunity, thereby enhancing the quality of life by addressing the dissonance between the individual's wishes and the imposed environment. At other times, addressing interpersonal tensions between residents may be the focus of treatment. A men's group may have particular value in institutional settings in which men are in the minority and feel isolated and particularly distant from former pursuits and interests.

Objectives of groups for burdened caregivers include education about the illness process and specific ways of providing care with the acquisition of strategies for dealing with disruptive behavior and problem-solving and stress-reduction skills. Working through loss and grief and facilitating appropriate disengagement that may lead to more realistic decisions about placement are also important objectives. Additional areas of focus include legitimizing the needs of the caregiver and promoting self-care, working through anger and guilt, and addressing relationships with healthcare professionals. These objectives may be integrated or addressed in a series of modules emphasizing important aspects sequentially.

Groups for the cognitively impaired aim to reduce excess disability and foster more appropriate social behavior and social functioning, thereby optimizing the quality of life. Groups that emphasize creative expression aim to restore a sense of competence and mastery through the activity be it art, drama, sculpting, or dance. Wellness and exercise groups aim to maintain patient well-being through physical activity and stress reduction provided in the context of a social milieu.

ETHICAL ISSUES

Proper patient selection and preparation and competent therapist functioning contribute to an environment that is generally well tolerated and experienced by participants as respectful and helpful. There is growing awareness of the differential impact group therapists can achieve, even when applying the same model of intervention. The interplay of therapist attributes and models of care may result in wide differences in impact.

Ethical care demands the therapist commit to ongoing training, evaluation of one’s clinical impact, and supervision or consultation. The ending of a group may be resisted because of the important social support and self-restorative experience offered by the group and because it provides a sense of stability and consistency in the face of the participant’s many life changes. This necessitates an active focus on the transfer of skills gained in treatment into the external world, recognizing that treatment is a bridge and not a destination. Therapeutic groups must be well integrated collaboratively into the overall milieu in which the individual resides.

Alterations in the frame of group therapy required within institutional settings, along with other factors that contribute to a higher likelihood of extragroup contact both occurring and even being endorsed, warrant special attention to issues of confidentiality. Extragroup contact and the risk of subsequent subgrouping may be managed by diminishing secretiveness around the extragroup relationships and actively bringing them to the attention of the group

Societal stereotypes of aging often lead to barriers hindering older adults from being referred and appropriately treated. For too many, the idea of aging stirs up feelings of loss, deterioration, and chronic medical illness, and challenges the needs of a culture obsessed with youth and youthful physical beauty as opposed to the beauty that reflects self-acceptance and the wisdom from a life well lived. Ageist beliefs among group members themselves can interfere. It is common to hear myths such as “depression or dementia is an inevitable part of aging” and “I am too old to change.” The misperceptions must be identified and worked through in the group. As a result, attention to therapist countertransference and reactions to the clinical work is particularly important in the practice of group psychotherapy. Realistic expectations guard against such negative countertransference as denial, hopelessness, and therapeutic despair. A reflective capacity for self-examination is particularly important in working with older adults because of potential issues of identification with patients, filial countertransference, and avoidance of the issue of sexuality.

An example of reflective capacity on the part of the group leader is offered in the Mr. K vignette. The group leader permits addressing the topic of romantic and sexual desires. The ethical issue involves balancing the needs of individuals with dementia with the needs and concerns of those around them, including their adult children.

Mr. K, a 75-year-old widower with minimal cognitive and physical impairment, became attracted to Mrs. B, a 73-year-old widow with moderate dementia of Alzheimer type. They began spending much time together and even expressed a mutual wish to get engaged. Mr. K in the group shared that “We want to be always together. We kiss now, maybe one day we’ll do more, but I wouldn’t want to touch her if she wouldn’t want me to. I would respect her feelings.” The couple went on to discuss how Mrs. B’s family wanted to break up the relationship as they believed Mr. K would exploit her and that if she was more cognitively intact, she would remain loyal to her deceased husband. Group discussion focused on how to honor both the obligation to promote autonomy and dignity and to offer protection when needed and whether it is possible to balance both ethical principles. Several ethical issues are raised: Is it appropriate to apply the usual consent to medical treatment to consent to sex? Should cognitive capacity be the sole and/or main determinant of whether or not a sexual relationship should be interfered with by adult children or nursing home staff or management? Under which circumstances, if any, should the family be notified; and should a person’s prior self take absolute precedence over the desires of the person now with some degree of dementia who still retains the ability to consent?

Group therapy is compatible with clinically indicated pharmacotherapy or individual therapy. Its concurrent use is complementary and not antagonistic. However, a collaboration between treatment providers is the critical, at times neglected component of effective conjoint therapy.

An additional important ethical concern relates to the removal of barriers to access to care that are rooted in ethnic and cultural patient factors. The concept of cultural competence is gaining prominence in the field of mental health as an important variable influencing treatment effectiveness. Cultural competence relates to the therapist’s appreciation for and understanding of the patient’s specific cultural context regarding illness, aging, mental health, family relationships, and, of course, treatment. The ideal group therapy will be provided in the primary language of the participants and in accessible settings within the specific communities. Recognition of crosscultural factors may require attention to the culturally resonant translation of therapy models.

RESEARCH AND EVALUATION

Group therapy in older adults is effective in treating a variety of disorders. There is a substantial evidence base behind modalities such as cognitive-behavioral (CBT) and mindfulness-based CBT treatments. There is also emerging literature on other group-based modalities, such as reminiscence therapy (RT), dialectical-behavioral therapy, schema-focused therapy, facilitated support groups, and care management for patients and their caregivers. Although the majority of this literature describes the delivery of these modalities in person, some literature describes the use of telephone and online platforms.

In a meta-analysis comparing the effects of psychotherapies for depression between different age groups, there was no meaningful difference between the effect size of psychotherapy between middle-aged adults (24 to 55 years), older adults (55 to 75 years old), and older adults (75 years+). In a systematic review ascertaining the effects of group therapy on geriatric depression, group therapy led to an improvement in geriatric depression, as well as other psychological variables, in a variety of settings, protocols, and participant characteristics. In the treatment of depression, therefore, older age alone does not prohibit from benefitting from psychotherapy. Furthermore, there may be common factors across modalities of group therapy that result in the improvement of older participants.

Group CBT is perhaps the best-studied modality among older adults and across a variety of psychiatric conditions. In a randomized control trial of older adults, group CBT demonstrated faster and sustained improvements in depression and anxiety in comparison to a control discussion group up to 6 months post-treatment. In another study, the use of group CBT, combined with duloxetine, showed a significant treatment response for generalized anxiety disorder in comparison to duloxetine alone. Telephone-based CBT also has demonstrated superiority in comparison to supportive therapy, treating anxiety symptoms among older adults up to 1-year post-treatment. Furthermore, culturally adapted models of CBT have shown promise in alleviating worries and anxiety over dementia among older Chinese adults when compared to treatment-as-usual. Group-based CBT also has evidence in treating post-traumatic stress disorder (PTSD) among older veterans and substance-use disorders. Lastly, an adapted version of CBT has been used for patients with mild cognitive impairment and their caregivers and has been found to help patients accept their illness, with female patients showing a decrease in helpless cognitions. Overall, group CBT appears to be helpful for older adults.

Group mindfulness-based CBT treatments, often referred to as “third-wave” therapies, have also been shown to be effective in treating older adults. One meta-analysis of mindfulness-based therapies for older adults showed a moderate effect size in treating depressive symptoms. Another meta-analysis of mindfulness-based stress reduction (MBSR) has shown effectiveness in reducing depression in older adults but concluded there was no clear evidence about the results extending to anxiety and stress. Another version of mindfulness-based CBT, MBCT, has been tested in randomized control trials and shown to be effective for anxiety symptoms in older adults in residential care. Overall, various group mindfulness-based treatments are effective in treating depression and possibly anxiety in older adults. Limited evidence exists for their effect on other psychiatric disorders, but it may be promising work in the future.

RT was introduced in dementia care in the 1970s and involved the use of discussion of past activities, events, and experiences, with the aid of tangible prompts. Reminiscence may be carried out in individual or group formats. While individual RT has been shown to have a small positive impact on cognition and quality of life, the studies of group RT have not shown this, suggesting that the mode of delivery is important in RT. However, group RT may have a positive effect on the communication of the patient with dementia, though the effect is small. Similarly, there is limited research to support group RT on depression, and anxiety in older adults in long-term care, as found in a systematic review. Group RT may have an adjunctive role in dementia care and other disorders but may not be sufficient as a stand-alone therapy.

A review of two randomized clinical trials using DBT skills training groups as an augmentation strategy of antidepressant medication to treat chronic depression and personality disorders in older adults demonstrates significant advantages for decreasing remission rates for medication and DBT compared to medication alone in the treatment of chronic depression. As well, DBT plus medication demonstrates superiority compared to medication alone in decreasing interpersonal sensitivity and interpersonal aggression at post-treatment and 6-month follow-up in a sample of older adults with comorbid depression and personality disorder. Research is underway to explore the effectiveness of the DBT model that has been modified to better meet the needs of the older adults.

A multicenter RCT of group-schema–focused therapy enriched with psychomotor therapy for older adults with cluster B and C personality disorders is currently underway and offers to enrich our understanding of treating personality disorders in later life.

A systematic review of group and individual cognitive intervention programs for individuals with amnestic mild cognitive impairment demonstrates comparable efficacy of both training formats. Statistically significant improvement after either treatment is obtained in objective memory and on subjective measures of memory, quality of life, or mood. It is suggested for further research to combine group and individual approaches as both approaches have unique benefits.

Participatory group-based case management seemed to decrease loneliness among those living alone in a randomized control trial of older people living alone. Furthermore, groups for burdened caregivers generally demonstrate that participants are very satisfied with the group experience. Complexities in the measurement of subjective and objective burden, coupled with the likely progressive deterioration of the care recipient, may confound other outcome measures. The acquisition of knowledge is easy to measure and demonstrate. Reductions in burden are harder to demonstrate. Both professional- and peer-led groups show significant effects, with the former tending to emphasize the provision of information and problem solving and the latter emphasizing peer support and networking. The best results emerge from integrative interventions that employ a broad focus, recognizing that there are multiple domains of concern for caregivers. This is consistent with a summary of the reviews of the caregiver intervention literature that demonstrates that more recent intervention studies are more effective when they employ combined interventions that target both the caregiver and the patient.

A pilot study of evidence-based interventions for family caregivers of individuals with behavioral and psychological symptoms of dementia demonstrates improvements in caregivers' self-perception of competence, significant reductions in emotion-focused coping, enhanced mastery, and reduced burden. Caregivers with more compromised baselines benefited most from the intervention comprised of three integrated components: group psychotherapy, problem-solving techniques, and skill acquisition for specific current challenging interactions in caregiving. The systematic use of standardized patients to role-play the spouse or parent with dementia is employed. Limitations of the study include the lack of a control group of carers and no outcome measures for care recipients.

Online delivery is an emerging modality for leading group psychotherapy but is scarcely researched. The COVID-19 (coronavirus) pandemic resulted in the rapid application of online groups for treating psychiatric conditions. Online groups provide several benefits, including improved access to care and cost-effectiveness, though they also pose several challenges, including confidentiality, access to technology, and managing core therapeutic tenets (i.e., managing the therapeutic frame, adapting to a lack of physical presence, and body language). There may be additional challenges for older adults as well who may not be familiar with online technology.

FUTURE DIRECTIONS

We can reliably anticipate an ever-increasing need for effective and meaningful group therapy interventions for the older adults and their families. Challenges and opportunities that lie ahead include creating models of intervention that are culturally accessible to a heterogeneous population of seniors. The field will also need to develop and test interventions for mood disorders that address common comorbid conditions, including anxiety, substance abuse, personality disorders, and, of course, cognitive impairment. In an allied fashion, we will need to develop integrative group interventions for the treatment and management of patients with dementia and their families, both together and separately. Groups for caregivers, both family and professional, of older adults with late-life psychiatric and medical illness and behavioral and psychological symptoms of dementia also need to be developed. In all domains, greater efforts will need to be made in the training of group therapists as we link theory to practice to empirical evaluation of the therapy.

55.4I Counseling and Support Needs of Dementia Caregivers

Liat Ayalon, Ph.D., and Patricia A. Areán, Ph.D.

INTRODUCTION AND DEFINITION OF CAREGIVING

What does caregiving mean? Webster's online edition defines a caregiver as "a person who provides direct care (as for children, older adults, or the chronically ill." A caregiver may be either a family member or a friend who provides informal care or a formal caregiver who receives money for their services. While anyone may assume the function of a caregiver, a primary caregiver is a family member or a friend who provides care to a person who can no longer take care of themselves. Although the reasons for assuming these responsibilities vary between the two types of caregivers, the burden of caring for a person with dementia (PWD) is high for both types of caregivers. Currently, informal caregivers are the majority of the caregiving population, and in most cases, care is provided either informally or through a collaboration of formal and informal carers. According to the Alzheimer's Association, in 2020, more than 16 million informal caregivers provided care to individuals with Alzheimer disease (AD) and other dementias. This has a tremendous economic value amounting to $305 billion and 18.6 billion hours of care. Caregivers of PWD provide substantially more care compared with caregivers of individuals with cognitive impairment or caregivers of people who are cognitively intact. Given the increase in life span, the decrease in childbirth, the entrance of women into the workforce, the high divorce rate, and the transition into nuclear family living, it is expected that formal long-term care alternatives will become more popular in future years.

Who is most likely to be a caregiver? Based on the Alzheimer’s Association, one in three caregivers of PWD is 65 and older, and almost 66% are women. About two-thirds of the caregivers live with the PWD. About one-quarter care for a child under the age of 18 in addition to caring for a PWD, thus representing the “sandwich generation.” According to the National Alliance for Caregiving (NAC/AARP), 30% of all caregivers also cared for children younger than 18 and, thus, are torn between caring for an older relative and younger children.

Researchers found no demographic differences between caregivers of individuals with dementia and those with milder cognitive impairments. Most caregivers of dementia patients care for people with AD, although a fair number also care for people with Lewy body disease, frontotemporal dementia, and vascular dementia. Each of these illnesses poses a unique set of problems for caregivers. AD is typically characterized initially by memory impairments, but as the illness progresses, it can result in personality and behavioral changes that may be upsetting to caregivers. Lewy body disease shares this same course but is coupled with physical disability related to tremors and unusual hallucinations that many caregivers find hard to understand and manage. Frontotemporal dementia is particularly vexing, as patients who develop this illness tend to be younger and physically healthy (men in their 50s), and while their memory remains intact for a long time in the course of the illness, behaviorally these patients become impulsive, inappropriate, and highly agitated. These disorders are not mutually exclusive. A person with AD may also have vascular disease; a person with Lewy body disease may also develop frontotemporal dementia. The more complicated the dementing illness in the patient, the more caregivers have to contend with. Because AD is the most common dementia afflicting older people, caregivers of persons with AD have received the most attention, with the majority of research focused on informal caregiving.

The Mental Health Consequences of Caregiving

Caregivers are generally at greater risk for mental health and health problems than noncaregivers. A recent systematic review has shown that women, married caregivers, and those providing intensive care are most likely to be negatively affected. Consistently, those caring for older adults with dementia tend to present with more negative emotional consequences compared with those who care for older adults who do not suffer from dementia. The most common mental health consequences of caring for a PWD are depression, anxiety, and a condition called *burnout.* These three conditions are often lumped together under the term *caregiver distress.* Studies find mixed results as to which condition is most common. It is largely believed that depression is the most common mental health consequence of caregiving. The Aging, Demographics, and Memory Study (ADAMS) found that as many as 44% of the caregivers of PWD were depressed, but only 27% of the caregivers of older adults with cognitive impairment but no dementia indicated depressive symptoms. Others have shown that as many as 40% of caregivers of older adults with AD are depressed, but only 5% of noncaregivers report depressive symptoms and meet the clinically significant cutoff of depression.

It is important to note that burnout is not necessarily the same condition as depression or anxiety, but these conditions do co-occur. According to Schulz, caregivers of PWD are particularly susceptible to burnout, a psychological and physical state of exhaustion resulting from excessive and prolonged stress. Caregivers who are family members are particularly susceptible to burnout, and many speculate that this emotional consequence of caregiving explains why 90% of elder abuse is committed by family members. Stress and burnout are not one and the same. People under stress can generally feel hopeful about the future, and when no longer in the stressful situation, they begin to feel like their normal selves. Burnout is far more severe and is characterized by frustration; feeling powerless and hopeless; feeling drained of emotional energy; becoming detached from others, which results in withdrawal and isolation; and feeling trapped, irritable, and sad.

Caregiver distress, be it depression, anxiety, or burnout, does not necessarily remit after caregiving responsibilities end. According to Carol S. Aneshensel and colleagues, caregivers who are less distressed before the death of the care recipient tend to have better mental health outcomes, whereas caregivers with significant emotional distress while caregiving tend to become even more depressed after the loss of the care recipient. Caregiver burden before death tends to increase the odds of becoming depressed; self-esteem and emotional support tend to have protective roles. A recent systematic review has highlighted the need to acknowledge that there also are positive aspects associated with caring for a PWD, which should be acknowledged.

The Effects of Caregiving on Physical Health

In addition to mental health consequences, there is a notable increase in poor health outcomes in caregivers. Compared with caregivers to older adults without dementia, caregivers to older adults with dementia are more likely to say that caregiving worsens their health. Some researchers speculate that poor health outcomes are the result of poor healthcare behaviors; caregivers generally do not have sufficient time to attend to their own medical appointments, and therefore potentially preventable health problems arise, such as hypertension and heart disease. Recent research also suggests that the stress related to caregiving may also influence health outcomes. Brent T. Mausbach and colleagues found that an exaggerated plasma norepinephrine response in caregivers is linked to an increased allostatic load related to cardiovascular disease. These researchers have also associated caregiver stress with reduced immune cell ss2-receptor sensitivity and increased D-dimer marker of hypercoagulability. Roland von Känel and colleagues have also found that caregiver distress is associated with increased frailty, affecting interleukin-6, C-reactive protein, and D-dimer. Janice Kiecolt-Glaser and colleagues found that caregiver distress has a direct effect on immune function through increases in the proinflammatory cytokine interleukin-6. Taken together, these studies suggest that morbidity and mortality related to caregiving have a physical basis and that beyond mental health consequences, caregiving distress has significant and direct impacts on health.

HISTORY AND THEORETICAL ISSUES

Attention to the needs of informal caregivers has been increasing over the past three decades. This is primarily due to the changing demographics and the realization that caregiving to older adults with dementia carries substantial economic, emotional, physical, and relational tolls. Several theoretical models have been offered to account for the negative effects associated with caregiving. Most theoretical models explain caregivers' burden, depression, and ill health by proposing a relationship between primary stressors, such as the older adult's functional or cognitive impairment, and the caregiver's outcomes. This relationship is thought to be mediated through the amount of informal support provided by the caregiver and the use of formal support.

TECHNIQUES FOR PREVENTING AND MANAGING CAREGIVER DISTRESS

Intervention models are often based on the above-detailed conceptualization of caregiver distress, and many are multicomponent models that address several risk factors, including education about the dementing illness, emotional support, information about resources, and counseling in the form of skills training, anger management, and mood management. The most widely studied interventions are skills-training classes, educational interventions, and support groups. Interventions that are administered over a long period of time and target the entire family are considered particularly effective.

Skills-Training Classes

There is considerable evidence in support of the efficacy of structured classes aimed at educating caregivers in stress management, anger management, and self-care. These interventions typically are multicomponent in that they teach caregivers about the causes of dementia, explain the reasons for behaviors they will see in the care recipient, and provide them with strategies for managing their anger, mood, and burden. Most of these interventions are behaviorally focused; they teach caregivers how to refocus their understanding of the care recipient’s behavior, make use of stress-reduction strategies like meditation and relaxation training, increase pleasant activities, and find opportunities to take a break from their caregiving responsibilities. The success of these interventions is very well documented. According to Mary Mittelman and colleagues, interventions aimed at mediating the factors related to caregiver distress (coping, appraisals, support) have significant effects on distress even 4 years after treatment. Interventions aimed at anger management and burnout are also effective. According to David Coon and colleagues, anger management and skills-building interventions have positive impacts on caregiver appraisal and self-efficacy.

Skills-training classes appear to be effective across ethnic groups. According to one study, a multicomponent intervention that targets stress management and self-care strategies was better than education and support alone in Caucasian, Hispanic, and African-American caregivers. Caregivers with low-pretreatment self-efficacy seemed to respond better to these interventions than those with high self-efficacy, although, across groups, everyone experienced benefit from these skills-building groups. One of the largest studies of caregiver treatment is the REACH trial, a study of 167 caregiver–recipient dyads, which found that coping and stress management classes were far more effective in managing caregiver depression and burden than interventions focused solely on how to manage behavior related to dementia. These findings were robust for 2 years after caregivers participated in the coping skills interventions. The REACH trial has also been shown to improve self-reported health status.

Education and Support Groups

Research shows that even minimal education classes that focus on caregiver-coping strategies and information about dementia have benefits for caregivers in mitigating distress. In one study, a minimal information control condition was compared to a skills-building program for African-American and Caucasian caregivers. The Caucasian caregivers benefited from the information control condition better than the skills-building condition, indicating that even the provision of information about dementia and caregiving can have substantial benefits to caregivers. Robert Woods and colleagues compared a mental health nursing program to support caregivers to community educational programs and found that community educational programs were as effective in reducing caregiver distress as the more intensive nursing program. A recent review has suggested that psychotherapeutic techniques in conjunction with educational interventions are most effective.

CLINICAL ISSUES

Indications

Not everyone who cares for a PWD feels the experience is a negative one. Some people, while experiencing some stress, are able to cope well with the role of caregiver. Spouse caregivers are more likely to report depressive symptoms, greater financial and physical burden, and lower psychological well-being. This is only partially accounted for by the fact that spouse caregivers also provide more hours of care. Compared with men, women caregivers are more likely to report depressive symptoms. Those caring for older adults with frontotemporal dementia are more likely to report distress and strain compared with caregivers of older adults with AD. Other studies have shown that certain ethnic groups cope better with caregiving than others; for instance, Hispanic and Black caregivers are more likely to report high levels of burden compared with White and Asian caregivers. A number of caregiver characteristics seem to be related to whether or not the caregiver will be distressed by their responsibilities. The most notable and well-studied characteristics related to the development or prevention of caregiver distress are the caregiver's culture, coping style, social support, and formal support; the relationship between the caregiver and care recipient; and, finally, characteristics of the care recipient. While each of these factors contributes to distress, most researchers agree that these factors interact with one another, and no one factor alone contributes to caregiver distress.

Limitations

One of the most complicated aspects of treatment for distress is access to these effective interventions. Several studies show that caregivers rarely feel they have time to devote to their own well-being. A number of studies have been done to see if telemedicine-type support could benefit caregivers. The studies have largely been mixed, indicating that simple telephonic support does not result in as good outcomes as in-person group support. However, a study of 299 caregivers receiving a multimedia caregiver intervention over the Internet found that Internet interventions of this nature provided a low-cost, convenient, and effective means of overcoming caregiver distress, as well as being flexible enough to tailor the intervention to the needs of the caregivers. Further, web-based support combined with in-person caregiving groups appeared to have a substantial impact on depression in 225 caregivers. Finally, Sara Anne Smith and Paul Bell studied a CD-ROM plus printed material intervention for rural caregivers and found this intervention to result in greater use of available support services, use of behavioral interventions to manage care-recipient aberrant behavior, and reductions in distress. Research of this nature is beginning to show that access to effective psychosocial interventions is possible for caregivers. However, a recent systematic review found only low levels of support for the efficacy of Internet-based supportive interventions.

Mrs. Y was a 56-year-old Caucasian woman whose husband of 30 years was diagnosed with AD 3 years ago. Over the years, Mr. Y had become increasingly forgetful and impulsive, often leaving food on the stove to burn, walking to the corner store and becoming lost, and buying expensive items that the family did not need. In the last year, Mr. Y bought two new cars and three high-definition televisions, despite the fact that he already owned a 2-year-old car in good condition and the Y did not watch television. Since Mr. Y's dementia became more apparent, he had to stop working, and Mrs. Y, as a consequence, also had to cut back on her working hours to accommodate Mr. Y's needs. In addition to Mr. Y's forgetfulness and impulsivity, his sleep patterns also became disturbed, and he often woke at night and wandered around the house, which disturbed Mrs. Y's sleep.

Mr. and Mrs. Y had two children, both of whom lived in different states; thus, Mrs. Y had to cope with caregiving demands on her own. As a result of a part-time job and an increasing worry that leaving Mr. Y at home alone would result in either a fire in the home or more unnecessary excursions to car dealers and electronics stores, Mrs. Y became quite distressed and experienced several colds and cases of flu that she was not able to care for. One such illness resulted in a case of pneumonia, and it was at this point in time that Mrs. Y came to the attention of the clinical team.

Although Mr. Y had ongoing neurology appointments in a prestigious university hospital, it was clear that Mrs. Y had not made use of the resources available to her through this service. Her reason for not attending the support groups, working with the social worker to link her to respite care, and making use of community resources was her lack of time between taking care of Mr. Y and her work to help support them financially. While in the hospital, the team social worker visited Mrs. Y to talk to her about the importance of making use of available services and the need to care for herself first so that she could then better care for Mr. Y. From this discussion, it was clear that Mrs. Y had become depressed and burnt out. Not only was she suffering physically from her caregiving responsibilities, but she was also feeling less interested in usual activities, had lost her appetite, had begun feeling hopeless and helpless, had trouble concentrating at work, and wished she or her husband would die. This last symptom left her feeling incredibly guilty; she loved her husband, and although forgetful and impulsive, he remained a loving companion to her. She was also clearly resentful toward her children; when she entered the hospital, her daughter had reluctantly flown in from her home to care for Mr. Y and had made it clear she would only stay until Mrs. Y returned from the hospital.

A clinical team began to work on reducing Mrs. Y’s caregiver distress in the following way. First, the social worker began to make arrangements for Mr. Y to attend a day treatment program that would provide services within the Y’s financial means. Mr. Y’s schedule would be mapped to Mrs. Y’s work schedule so that she would not have to worry about Mr. Y being home alone. Temporary evening respite care was also arranged while Mrs. Y recovered from her pneumonia. This respite care was eventually reduced to 1 day a week so that Mrs. Y could have time for herself and attend a skills-building class for dementia caregivers. Mrs. Y was reluctant to join the class—in fact, she only attended intermittently; however, she did make use of the neurology department’s online caregiver support program in conjunction with the occasional classes and reported that she found the website helpful.

Six months after her hospitalization for pneumonia, Mrs. Y was feeling both physically and emotionally better. She still struggled with her husband’s increasing dementia but had become more active, re-engaged with friends, and was more productive at work. One year after her hospitalization, Mr. Y was moved to an assisted-living facility because of his rapidly deteriorating condition. Mrs. Y then joined a caregiver support group, as she missed her husband and was dealing with guilt related to assisted-living facility placement. This group was particularly useful to Mrs. Y in helping her see this placement as a necessary step in her and Mr. Y's health, gave her strategies for making her visits to Mr. Y pleasant, and reinforced her need to remain connected to her friends.

Goals of Interventions

Given the diverse nature of the various caregiving interventions, potential goals for treatment are also diverse. Goals may include increasing knowledge about dementia, improving the caregiver's coping skills with problem behaviors, reducing caregiver burden, depression or anxiety, increasing well-being, reducing the care recipient's problem behaviors, or increasing social support. The exact intervention goals should determine the intervention offered.

ETHICAL ISSUES

Caregivers of older adults with dementia face multiple ethical challenges. As the disease progresses, dementia caregivers have to make decisions about various treatment options, end-of-life care, and participation in drug trials. Some of these issues are likely to surface, during treatment, as a source of great distress and agony to some caregivers. A different ethical issue that should be addressed by researchers is the amount of burden put upon caregivers of PWD, who often accompany their loved ones during drug trials and, as a result, become secondary participants in dementia research.

RESEARCH AND EVALUATION

Successful interventions exist, with the majority of caregiving interventions including both a supportive and an educational component. Longer interventions tend to be more effective than shorter ones. More attention should be placed on clinically significant interventions rather than merely statistically significant ones. There is also increasing interest in establishing consensus on outcome measures for caregivers' interventions. In the past, access to interventions was complicated by the fact that caregivers, who rarely feel they have time to attend classes, were not likely to take the time to attend these sessions. Recent research suggests that interventions can be successfully delivered over the telephone and the Internet. However, these interventions may not meet the need for social support so often present among caregivers of older adults with dementia, and their efficacy should be further examined.

55.5 Financial Issues in the Delivery of Geriatric Psychiatric Care

Steve Koh, M.D., M.P.H., M.B.A., Helen H. Kyomen, M.D., M.S., Michael Hann, M.D., M.B.A., M.S., C.P.E., F.A.C.H.E., F.A.P.A., and Hilary Gould, Ph.D.

Mental health financing for the aging population is complex and compounded by multiple economic factors. While Medicare and Medicaid are cited as examples of a single-payer system in the United States, the costs of an aging population are increasing, and mental health care remains underfunded. This is further complicated by growing financial concerns for individuals who are facing not only rising health care costs but also higher living expenses during a time of decreased income and diminished savings. Despite the passage and implementation of legislation that ensured mental health parity—the Patient Protection and Affordable Care Act (PPACA), health care costs continue to be a significant percentage of total personal and governmental expenditures. One reason for this is that monitoring and enforcement of parity are inadequate and often left up to each state. Consequently, mental health care continues to be carved out from general health care coverage, and older patients may find themselves picking between certain medical treatments and daily living expenses. Additional financial burdens on households may emerge, including becoming caregivers to loved ones with chronic illnesses. Economic factors such as payment mechanisms and funding sources are key determinants of access to geriatric psychiatric care and health care delivery services and the actions of providers.

Since the 1990s, government, and industry have sharpened their focus on health care expenditures, and it has become clear that cost-effective health care cannot ignore comorbid mental illness. Now widely recognized as a cost multiplier when present as a comorbid condition, the need for improved mental health treatment to achieve better outcomes has been reported by multiple sources. The mental health treatments requiring different financial support can include those related to physician services, levels of care, collaborative care, substance use treatments, memory care centers, pharmacy costs, and preventative care. Ongoing attention to the Triple Aim of health care continues to drive innovation: improving the health of a population, increasing quality outcomes of individuals, and lowering the cost of care delivery. While still far from an ideal solution, the rise of accountable care organizations (ACO), financial models pertaining to value-based outcomes, and cost-effective treatment models serve to give hope for the future. These developments highlight the relationship between patients, providers, and larger systems crucial in providing optimal care for older adults.

DEMOGRAPHIC TRENDS AND THE COST OF HEALTH CARE FOR OLDER ADULTS

Rational planning for mental health care services for the future requires an understanding of the magnitude and diversity of the projected growth patterns in the older adult population in the United States. Furthermore, the differences between sexes and ethnic groups are important to note as there continue to be significant financial resource differences between them. In the mid-1950s, only 1 of every 11 Americans was older than the age of 65. In each of the last several decades, the proportion of older adults has grown substantially. By 2000, there were more than 35 million people aged 65 and older, constituting approximately 12% of the American population. Since then, the growth of the baby boomers has contributed to more than 52 million adults over the age of 65 in 2018. By 2034, for the first time in the history of this country, older adults are expected to outnumber children, accounting for approximately 20% of the total population. By 2050, it is projected that there will be 88.5 million individuals over the age of 65. This is not unique to the United States. The United Nations estimates that by 2050, 21% of the total global population will be above the age of 60. Additionally, the number of oldest-old adults (i.e., 85 years of age and above) continues to increase. It is expected that by 2040, 14.4 million Americans will be among the oldest.

The differences in the number of older men versus women will have important economic consequences. The economic effects of lower educational levels, traditional work roles, and income discrimination experienced by women in young and middle age will be exaggerated as retired women depend on pensions and social security derived from preretirement income. Currently, older women outnumber men by 29.1 million to 23.3 million. While in 2013, the ratio of older males to females was 76:100, by 2050, it is projected to increase to 87:100. This is due to continued increases in life expectancy for both sexes and improved health care. With increased longevity often comes greater health care needs. Many older adults need home care at some point, and it is estimated that even after liquidating all assets, only 40% of older adults with disabilities can afford just two years of home care. As the cost of care increases, the ability to keep older adults in their homes will diminish, and the expense will shift to governmental agencies. Additionally, elements that make up social determinants of health cannot be ignored. Research indicates that stable housing and home ownership have a direct correlation to self-rated health. Poor self-rated health ratings were directly related to higher health care costs and poor outcomes.

Similarly, ethnic minorities make up a growing proportion of the older-than-65 population. In 1990, approximately 11% of people older than 65 in the United States were of non-White ethnicity (non-European descent). In 2018, 23% of older Americans were members of a racial or ethnic minority, which is approximately 12.3 million individuals. This is expected to increase to 27.7 million by 2040. Currently, older African Americans make up 9% of the population, while Hispanics represent 8%. It is expected that older Hispanics will become the largest ethnic minority group by 2030. This change has been due to decreases in the rates of human immunodeficiency virus, heart disease (in women), homicide, and unintentional injuries. Still, many older African American individuals have considerably higher rates of poverty, illness, and violent deaths than Caucasian individuals in the same age group. The economic and social discrimination of the chronic underprivileged associated with American minority status is exaggerated by the socioeconomic consequences of older age. In this population, accrued social and financial resources are limited; access to preventive and acute health care is poor; and the likelihood of exposure to tobacco, alcohol, other toxins, and violence is higher. In addition, barriers to government services such as housing, transportation, meals, and income maintenance are more prevalent. All of this results in a cycle of medical, economic, and social poverty that affects the quality of life and has a substantial impact on the provision and financing of geriatric psychiatric care for older adult minorities. Further compounding this situation is the fact that there are significant state-to-state discrepancies in ethnic minority life expectancies. Currently, there are 3,428 medically underserved areas/populations in the United States. For mental health services, about 37% of the U.S. population is living in areas with mental health professional shortages. In these areas, the utilization of emergency and a higher level of care is high and adds to the financial cost of care.

Retirement from employment has important effects on economic status, access to health care, and insurance. Retirement reduces personal income and increases reliance on government assistance and retirement plans. Reduction in income after retirement threatens the stability of social class for older people and increases the likelihood that some people will experience economic poverty for the first time in their later life. These poverty prevalence rates are noticeably higher for women and minorities. In 2013, over 4.2 million older adults were below the poverty level based on income alone. If regional variants in cost of living, noncash benefits received, and nondiscretionary expenses are considered (the so-called Supplemental Poverty Measure from the U.S. Census Bureau), the poverty level of older persons reaches 14.6%. In 2019, these numbers increased to over 4.9 million people aged 65 and older living in poverty. The percentage of those living in poverty increased with age. For example, 11.1% of those above the age of 80 were in poverty in comparison to 8.4% of those aged 65 to 69. Additionally, the poverty rate was 18.0% among those identifying as Black or African American compared with 17.1% for those identifying as Hispanics, 9.3% for the Asian population, and 6.8% for the non-Hispanic White population. A major contributor to this increase is high medical out-of-pocket expenses. This cost is magnified in geriatric mental health care and in long-term care, where out-of-pocket copayments, deductibles, and direct purchase of services account for a substantial component of total costs.

As long-term financial stability is questioned, many individuals are electing to delay retirement or continue to work part-time. Since the Great Recession (spanning from 2007 to 2009), the average retirement age has increased. Twenty percent of Americans continue to work past 65 years of age, compared with 10% in 1985. Even though median income typically peaks between the ages of 45 and 54, in more recent years, those above age 65 saw percentile increases in their median income. This indicates that more Americans are working into their 60s, particularly those with higher education and higher earnings. Yet, many indicate that there is added pressure (related to changing work environment and ageism) to retire despite their worry about long-term security. The single most important factor for concern about retirement is health care cost. Retirement directly affects health insurance premiums, the availability of certain insurance plans, and access to some health care delivery systems.

Overall fiscal impact on health care by the older population is undeniable. While their earnings are decreasing, the health care needs of the growing older population continue to rise. The cost of health care in the United States is far greater than in other industrialized nations. Older adults make up a significant proportion of this high cost. Almost half of all health care spending is consumed by just 5% of the population. In fact, older adults account for more than 36% of total health care costs. Those between 65 and 70 years of age represent 29%, and those above the age of 80 account for 14% of the top 5% of spenders. In general, medical spending doubles between ages 70 and 90. Among those with Medicare–Medicaid coverage, the older adults and disabled account for more than 70% of Medicaid spending despite representing just 25% of the Medicaid population. The top five most expensive health conditions to treat are heart disease, cancer, trauma, mental disorders, and pulmonary conditions. Twenty-five percent of the U.S. population reportedly has one of the top five chronic conditions (i.e., mood disorder, diabetes, heart disease, asthma, and hypertension). The rise in Medicare and Medicaid costs can be explained partially by the aging population and mental illness.

HISTORICAL BACKGROUND

Historically, government policy has been important in shaping the status of psychiatric care for older people. During the 19th century, financial responsibility for the care of the chronically mentally ill and people with major neurocognitive disorders was transferred from local to state authorities, resulting in the replacement of asylums and almshouses by the massive state hospital systems of the first part of the 20th century. Ultimately, deinstitutionalization in areas of limited community resources resulted in the transfer of a substantial number of older people with severe and persistent mental illnesses from state hospitals to community nursing homes with sparse psychiatric resources. Beginning in approximately 1965, reimbursement for nursing home care under Medicaid effectively shifted some of the financial responsibility for this population from states alone to the states and federal government.

The introduction of Medicare and Medicaid in the mid-1960s created a private market for older adult health care. Private practitioners and institutions were reimbursed fee-for-service at market prices by these insurance programs. Adequate financial returns for hospital-based services, reinforced by the growth of commercial indemnity insurance, drove the development of for-profit hospital care, particularly in freestanding psychiatry. Simultaneously, severe limitations in reimbursement for ambulatory psychiatric services under Medicare impeded the growth of private practice interest in geriatric psychiatric care while creating imbalanced incentives for the use of hospital resources. Federal-level sensitivity to these new expenditures and social concerns about inappropriate care led to the nursing home reform provisions of the latter part of the 1980s and to the formulation and implementation of a set of guidelines for the use of psychiatric interventions in that environment. The health care cost reform of the last generation has similarly reshaped geriatric psychiatric service delivery. In the recent past, Medicare was more attractive than some commercial payers to hospitals and individual providers. Nonpsychiatrist mental health specialists, newly eligible for participation in Medicare and other payment programs, created the availability of a greater diversity of providers, with psychotherapeutic services much more broadly available to older adults.

The passage of PPACA has led to high hopes for better health care coverage and cost savings. For older adults, it is not clear how remarkable financial improvements have been. In part, this is because the application of PPACA has been inconsistent across the states, and it did not significantly overhaul Medicare services for older adults. Access to mental health care seems to have improved with more funding for Federally Qualified Health Centers and federally funded programs like the Program of All-Inclusive Care for the Elderly (PACE), as well as the increased emphasis placed on mental health care services. The Medicaid expansion to cover more Americans at or below the poverty line has increased preventative care that has improved the lives of those entering older age. However, inequality in mental health care coverage continues due to geriatric provider workforce shortages, continued high out-of-pocket costs of mental health care, and poor access to geriatric psychiatric care. It is hoped that the ongoing rise in health care costs and the significant impact of comorbid mental illness will lead to more attention to innovative care models that will emphasize outcomes and overall value to the older population’s health.

MEDICARE SYSTEM

The Medicare program was established in July of 1965 to provide medical care benefits for older people participating in the Social Security program. Since then, a number of modifications have been made to the Medicare program, in both the Hospital Insurance program, Part A, and the supplemental Medical Insurance program, Part B, and through the development of Medicare Part C and Part D. The Medicare Prescription Drug, Improvement, and Modernization Act of 2003 provided the most extensive changes to Medicare since its initiation. In addition, the 2010 PPACA has contributed to fundamental changes in overall health care delivery, including Medicare.

In 1972, Medicare was expanded to cover younger people with disabilities and older adults outside of social security who were willing to pay a premium. In 1973, the program started to provide medical coverage for people with end-stage renal disease. In 1997, the Balanced Budget Amendment of 1997 (BBA 1997) established Medicare Part C, then known as Medicare+Choice. As part of Medicare Part C, the BBA authorized the Centers for Medicare and Medicaid Services (CMS, the replacement agency for the Health Care Finance Administration) to offer various health care options. Medicare Part C includes Medicare managed care plans (such as health maintenance organizations [HMOs], provider-sponsored organizations [PSOs], and preferred provider organizations [PPOs]); Medicare private, unrestricted fee-for-service plans, Special Needs Plans (SNP), Religious Fraternal Benefit (RFB) plans, and medical savings account plans.

In 2003, Medicare was extensively updated to include:

- Expansion and renaming of the Medicare+Choice program as Medicare Advantage
- Prescription drug programs and benefits, including a new program called “Medicare Part D”
- Medication therapy management programs for those with multiple chronic conditions, multiple prescriptions, and likely high drug

expenses
- Coverage of certain screening and disease management programs such as initial physical examinations and cardiovascular disease and diabetes screening
- Changes in reimbursements to hospitals and physicians, including ongoing refinement of the prospective payment system (PPS) for inpatient psychiatric care
- Improved rural health care provisions
- A demonstration project for recovery audits to identify underpayments or overpayments and collect overpayments, and
- Changes in the acquisition systems for durable medical equipment and other products to provide for a competitive bidding process

Medicare was designed to provide coverage for the treatment of acute conditions, and this has been the primary orientation of the program over the years. Medicare has not covered most preventive and pharmaceutical services since the program's inception. The Medicare Prescription Drug, Improvement, and Modernization Act of 2003 provided for some change in this focus with coverage of some preventive services and the addition of pharmaceutical benefits. Long-term care and dental services continue to be excluded from traditional indemnity Medicare. Other services, including mental health care, had been subject to limitations in payment and substantial copayments. The Mental Health Parity Act of 1996 (MHPA) ensured that large-group health plans could not set annual or lifetime dollar limits on mental health benefits, which are less favorable than any such limits for medical or surgical benefits. The Wellstone-Domenici Mental Health Parity and Addiction Equity Act (MHPAEA) of 2008, enacted into law on October 3, 2008, and effective for most health insurance plans on January 1, 2010, added additional protections. This law required that group health plans (with over 50 employees that offer both medical/surgical and mental health/substance use benefits) provide coverage for treatments of mental health/substance use disorders that is no more restrictive than the coverage for treatments of medical/surgical conditions.

Equity coverage is applied to financial requirements as well as treatment limitations. However, the MHPAEA does not require large group health plans or health insurance issuers to offer mental health or substance use disorder benefits.

In 2020, Medicare provided insurance coverage for 34 million older adults (97% of older adults in America). Growth in the older adult population, advances in medical technology, more extensive use of pharmaceutical treatments, and other increases in the cost of health care have contributed to the extraordinary growth in health care expenditures, both in the Medicare program and otherwise, that has occurred since the mid-1990s. Although health care costs have continued to grow, especially among older adults, various efforts to contain Medicare costs have been successful in slowing health care inflation rates. Each of these changes has profoundly affected access to appropriate psychiatric care for older people, and each has impacted the scope and configuration of geriatric mental health specialty care. Aggregate Medicare cost reductions have resulted from decreases in reimbursement levels of hospital and physician providers, increased requirements for out-of-pocket payments by Medicare beneficiaries, and substantial shifts from indemnity insurance to managed care. In addition, as part of the Deficit Reduction Act of 2005, CMS has been allowed since 2008 to begin adjusting payments for “never events.” Never events are “serious and costly errors in the provision of health care services that should never happen” and are characterized by “unambiguous,” “usually preventable,” and “serious” events that are “adverse” and/or indicate “a problem in a health care facility’s safety systems” and/or are “important for public credibility or public accountability.” Examples of never events include hospital-acquired severe decubiti, death, or serious disability related to a medication error, and death associated with falling while being cared for in a health care facility. Never events lead to increased health care costs due to the need to treat the consequences of the error. Additional Medicare cost reduction has been attributed to the PPACA of 2010 and sequestration, which started in 2013. Still, Medicare spending represented 20% of national health spending in 2013 and grew 3.4% to about $586 billion, which was a slowdown from a growth of 4.0% in 2012. This slowdown was thought to be due largely to slower enrollment growth and the impacts of the PPACA and sequestration. In 2020, Medicare spending grew 3.5% to $829.5 billion, about 20% of the total National Health Expenditure. From 2019 to 2028, Medicare is expected to have a spending growth of 7.6% per year due to projected high enrollment.

The Medicare program has several components: Hospital Insurance, or Part A, covers inpatient hospital care, skilled nursing facility care, limited home care, and hospice services. Part B, the supplemental Medical Insurance program, covers preventative care, services provided by physicians and other professional providers, durable medical equipment, ambulatory medical laboratory tests, outpatient rehabilitation care, and group therapy services in psychiatric hospitals. Part C includes Medicare managed care plans (such as HMOs, PSOs, PPOs, Medicare private, unrestricted fee-for-service plans, SNP, RFB plans, and medical savings accounts). Under Medicare Part D, Medicare beneficiaries have been eligible to obtain prescription drug coverage by enrolling in a private prescription drug plan or in an HMO or other plan that accepts Medicare capitation payment and offers a drug benefit.

Hospital Insurance (Part A)

Americans older than age 65 who participate in the Social Security program are entitled to Part A Medicare coverage. The Part A Hospital Insurance Trust Fund is supported by social security payroll taxes paid by employers, employees, and the self-employed. In 2020, over 39 million people had Medicare coverage, and at the end of 2020, the Hospital Insurance Trust Fund had assets of $134 billion.

Medicare coverage for inpatient care is limited to relatively brief inpatient stays, presumably for the stabilization of acute symptoms. Part A provides coverage for episodes, which are time-limited “spells” of illness. A spell is an episode of inpatient care that starts with hospital admission and ends after the first period of 60 consecutive days outside the hospital after hospital discharge. If a person is discharged and readmitted numerous times during a given episode of illness and has not been out of hospital for 60 or more consecutive days, they are considered to have remained within the same spell. For treatment of any condition in a general hospital, there is no limit on the number of spells or days covered within an individual's lifetime. However, no more than 150 inpatient days are covered during each episode.

The first 60 days of each spell are fully paid after a deductible equal to the national average cost of 1 day of hospitalization has been met. The next 30 inpatient days are paid at the same rate, less a 25% copayment. The last 60 days of covered hospitalization require a 50% copayment. Days 91 to 150 are identified as "lifetime reserve days." Medicare pays for those days during any single spell of illness but only once in a beneficiary's lifetime. For example, if a patient requires five hospitalizations totaling 110 days without a period of discharge of at least 60 days, they would have 40 days of remaining coverage in their lifetime for future episodes that last more than 90 days. Individuals may save these days for future hospitalizations and use other resources to pay for any part of the costs of days 91 to 150.

At the time that Medicare was first signed into law, there were large populations of older adult patients in state psychiatric hospitals. Federal legislators feared at that time that the enactment of Medicare would shift the burden of care for that population from state-supported resources to acute care facilities reimbursed with federal monies. Consequently, Medicare coverage for inpatient treatment in freestanding psychiatric hospitals was limited to a total of 190 days over the course of a person's lifetime. The law provides that if an individual becomes eligible for Medicare during a psychiatric hospitalization, the Medicare intermediary may deem that less than the full 150 days allocated for that spell of illness will be covered. Given improvements in treatment and increased life expectancy, this limitation can easily create undue hardship and compromise continuity of care. For example, a person with a recurrent major affective disorder who experiences several depressive episodes requiring inpatient care after age 65 could easily exhaust the lifetime freestanding psychiatric hospital benefit.

Part A provides coverage for nonacute services, including skilled nursing facility care, if these services are used briefly and for “remediable” conditions. For a beneficiary to obtain benefits for skilled nursing facility care, they must have been hospitalized for at least 3 consecutive days for an acute condition, and skilled nursing facility admission must follow within 30 days of hospital discharge. Medicare may fully cover up to 20 days and partially cover days 21 to 100 of skilled nursing facility care for each episode of illness. Similarly, coverage for home health services is limited to care for acute and remediable conditions.

From 1966 until 1983, Medicare Part A paid for hospital care using a retrospective cost-based reimbursement system. This system compensated providers on a fee-for-service basis for all those costs deemed allowable under Medicare without an incentive for utilization management. In 1982, after years of rapid and sustained growth in Medicare expenditures for inpatient care, the Reagan administration signed into law the Tax Equity and Fiscal Responsibility Act (TEFRA). TEFRA created incentives to reduce hospital payments by setting targets for operating costs, and it provided supplemental payments for compliance with specified objectives. Reimbursement was transitioned from a retrospective cost-based approach to a payment system designed to reflect patient mix, geographic location, and training costs. This TEFRA-mandated system is known as the PPS.

The PPS established by TEFRA uses diagnosis-related groups (DRGs) to classify patients who require similar care into major diagnostic categories and assigns each Medicare patient discharge to a diagnostic group. These groups are derived from principal and secondary diagnoses, procedures rendered, and, to a lesser degree, age, sex, complications, and discharge status. The DRG system was revolutionary in creating a “case-based” approach to reimbursement. Under the PPS, hospitals are paid a fixed amount for each case according to the corresponding DRG, regardless of the resources that are consumed during the hospitalization. If patients require extraordinary resources or extremely prolonged hospital stays, Medicare classifies the patient as an “outlier” and provides an additional payment to the hospital, although at a per diem rate considerably below actual costs. This set of conditions creates an incentive for hospitals to provide efficient care and create an infrastructure of ambulatory services that can shorten or substitute for hospitalization.

Several studies have indicated that, although DRGs are modestly effective in predicting use for medical and surgical diagnoses, their ability to predict use for psychiatric diagnoses is poor. Accordingly, the Health Care Finance Administration, the federal agency responsible at that time for Medicare/Medicaid fiscal management, exempted freestanding psychiatric hospitals and distinct psychiatric units in general hospitals from the DRG system until a fairer system could be ascertained. In 2004, a newly designed Medicare PPS for inpatient psychiatric services with updated psychiatric DRGs was established by the CMS. Under this new system, a federal per diem rate was established, providing for adjustments for changes in the hospital market basket index, age, comorbidities, and psychiatric diagnosis. In this system, 15 psychiatry-related DRGs were established, with weights ranging from 22% above average for DRG 876 (“Operating Room Procedure with Principal Diagnosis of Mental Illness”) to 12% below average for DRG 897 (“Alcohol/Drug Abuse or Dependence without Rehabilitation Therapy and without Complications and Comorbidities”). Currently, there are 12 psychiatry-related DRGs (i.e., DRG Codes 876–887; 896, 897).

Until the new PPS for inpatient psychiatric services was initiated, freestanding psychiatric hospitals and psychiatric units in general hospitals were reimbursed retrospectively by Medicare. Ever since TEFRA was implemented in 1983, payment for treatment in psychiatric units had been capped at a rate established for each facility based on use during its first fiscal year of operation after October 1, 1983. Until 1998, if the actual cost of care per case was greater than the capped rate, the hospital absorbed the loss. However, if the cost was less than the capped rate, a small incentive payment was retained by the hospital. The Balanced Budget Act

(BBA) of 1997 modified and limited these reimbursements by establishing differential caps, with or without wage adjustment. It also provided less generous bonuses and relief payments for PPS-exempt facilities. The Balanced Budget Refinement Act (BBRA) of 1999 addressed some of the flawed policies and excessive payment reductions resulting from BBA 1997. The BBRA of 1999 allowed for wage adjustments at the 75th percentile limit established by the BBA of 1997 for PPS-exempt facilities that received their first Medicare payment before October 1, 1997, and increased bonus payments for psychiatric hospitals. The BBRA of 1999 also stipulated that a new Medicare PPS for inpatient psychiatric services was to be initiated by April 1, 2004. The final rule establishing the PPS for inpatient psychiatric facilities was published on November 15, 2004, in the Federal Register. Since then, CMS has made periodic updates to the inpatient psychiatric facilities PPS. Under the Code of Federal Regulations 42 CFR 412.428, annual updates include revisions to the federal per diem base rate, hospital wage index, International Classification of Diseases (ICD) coding and DRG classifications, electroconvulsive therapy (ECT) payment per treatment, fixed dollar loss threshold amount and national cost-to-change medians and ceilings in urban and rural areas.

Supplemental Medical Insurance (Part B)

Medicare Part B is a medical insurance program that covers preventative care, services provided by physicians and other professional providers, durable medical equipment, ambulatory medical laboratory tests, outpatient rehabilitation care, and group therapy services in psychiatric hospitals. Medicare Part B is a voluntary program and requires a monthly premium payment for participation. Approximately 93% of Medicare Part A beneficiaries also participate in the Part B program. Part B is supported by the Supplementary Medical Insurance Trust Fund, which includes general revenues from the Treasury, as well as premiums. In 2022, the standard monthly premium for Medicare Part B is $170.10, and the annual deductible is $233. The Medicare Part B premium, deductible, and coinsurance rates are determined each year according to the Social Security Act.

Since the enactment of the MHPAEA, group health plans and health insurance issuers are required to ensure that financial requirements (such as copays and deductibles) and treatment limitations (such as visit limits) applicable to mental health or substance use disorder benefits are no more restrictive than the predominant requirements or limitations applied to substantially all medical/surgical benefits. The MHPAEA supplements prior provisions under the MHPA, which required parity with respect to annual and aggregate lifetime dollar limits for mental health benefits.

From 1984, after TEFRA and the PPS were initiated, until 1992, the rate of growth of Medicare physician costs was more than double the rate of growth for inpatient hospital costs. Policy analysts attributed this growth to uncontrolled price escalation and substantial increases in the number and intensity of services consumed. In 1989, inflation in physician-related costs and mounting evidence that physicians’ behaviors in treating complex medical illnesses were influenced by the high prices of the procedures they performed led to a sweeping reform of Medicare Part B through the Omnibus Budget Reconciliation Act of 1989 (OBRA-89).

OBRA-89 created standards for expenditures and procedure volumes to bring the total cost of physicians’ services under control. The law required the secretary of the United States Department of Health and Human Services (HHS) to identify specific volume performance standard growth rates for surgical, primary care, and nonsurgical nonprimary care services at the beginning of each fiscal year. These standards must be related to medical inflation and changes in the size of the Medicare population, as well as to changes in service volume and intensity. At the end of each year, the secretary must compare actual growth and expenditures with this volume performance standard and determine any changes in fee schedules for the following year. OBRA-89 also created a national uniform Medicare fee schedule to replace local methods that were traditionally used by intermediaries to set fees for each procedure and for each provider. In 1992, a Resource Based Relative Value

Scale (RBRVS) was developed to determine the relative values of approximately 7,000 physician procedures and services. In this scale, the relative value of each of these services is derived from three components: work, practice, and malpractice expenses, and the opportunity costs of postgraduate specialty training required. The proportion of each component in determining the relative value is based on a weighted average of specialty-specific practice expense and malpractice data. To change provider behavior and reduce incentives to perform highly reimbursed technical procedures, the work component is derived from estimates of the time intensity and stress associated with the delivery of the procedure. Approximately 60% of the value of each fee is adjusted for local costs. The product of each relative value and a monetary conversion factor determine the fee for each service.

OBRA-89 was a landmark for behavioral health in its provision for direct reimbursement of services provided by psychologists and social workers. It also sets criteria for nonphysician providers regarding consultation with a physician. Nonphysician providers must document that a patient has been informed that consultation with the patient's primary care physician (PCP) is desirable for the PCP to evaluate medical conditions that could contribute to a patient's well-being. The provider must also document any written or verbal communications with the PCP about treatment unless the patient specifically prohibits such contact. The law does not require consultation with a psychiatrist. The law stipulates that reimbursement of services provided by psychiatric nurses and other therapists requires direct physician supervision.

In general, direct patient contact is required for any reimbursable service. Consultation or other services rendered by telephone and renewals of prescriptions that do not include direct evaluation of a clinical condition have not been reimbursable. Medicare Part B allows billing for services required to obtain clinical information from relatives or close associates of unreliable or uncommunicative patients. Family counseling services are reimbursable only when their purpose is to facilitate patient care. With the direct in-person care limitations imposed by the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) and SARS-CoV-2 variant outbreaks starting in 2019, there has been more support for the reimbursement of telehealth services, especially on a state-by-state basis.

There are two ways in which providers may participate in Part B of the Medicare program:

1. A provider may accept the assignment and agree to accept the applicable Medicare fee as payment in full. Medicare's fiscal intermediary pays the provider the approved amount less copayment and deductible directly. The provider is legally required to bill the patient directly for the copayment and the deductible.
2. A provider may choose not to accept an assignment. Providers who do not accept assignments may charge patients up to 115% of the approved Medicare fee. Medicare reimbursement for providers who do not participate in Medicare Part B is limited to 95% of the approved fee, with fewer deductibles and copayments. The provider may then bill the patient directly for the balance of charges up to the 115% limit.

All providers must accept assignments from Medicare beneficiaries who also participate in the Medicaid program. The assignment must be accepted for all Medicare recipients who are at or below the federal poverty level, regardless of whether they have Medicaid as a secondary payer. In an increasing number of states, medical licensure authorities and insurance commissions require that all physicians who participate in the Medicare program accept assignments for patients seen within that state.

Medicare Risk in Managed Care

Since the early 1970s, Medicare has encouraged older Americans to enroll in capitated health plans. Since that time, HMOs have been able to contract directly with Medicare. Between 1985 and 1997, Medicare payments to risk-contracting HMOs for aged and disabled beneficiaries were based on adjusted actuarial estimates of the per capita cost of such services incurred in a beneficiary's county of residence, using adjusted average per capita cost (AAPCC) methods. The AAPCC had been based on the individual's county of residence, age, and sex and whether a patient is covered by Medicaid, lives at home or in an institution, and works or is retired or disabled. The county per capita payment rates are adjusted for the average beneficiary and have been published each year as the County Rate Book.

HMOs, although allowed to earn "normal profit margins," must use savings above a predetermined rate to provide extra services for older adult members. For many years, to penetrate a local market, HMOs frequently waived premiums and offered to include usually uncovered services in the benefits package to induce enrollment. Unlike traditional Medicare, HMOs allow access to primary care and other preventive services in the absence of a primary diagnosis. In addition, managed care plans usually provide coverage for some portion of outpatient pharmaceutical costs.

The nature of HMO risk-contracting with Medicare provides an incentive for HMOs to market to healthy older adult populations who are likely to consume services valued at considerably less than the 95% of AAPCC criterion used to set capitation rates. Indeed, healthy populations, even if older than 65 years, yield substantially greater profit margins for HMOs, leaving sicker, more disabled people to be cared for via direct payments from CMS in the traditional Medicare program. Several studies have indicated that capitated plans generally enroll healthier and less costly beneficiary populations than those who remain in fee-for-service Medicare. In one study, in the 6 months preceding enrollment, new members of capitated plans had health care costs that were 35% lower than the average costs of patients in traditional fee-for-service Medicare. Some plans profit through marketing to "younger older adults" (people aged 65 to 70) in settings in which there is a greater likelihood of health and independence. Studies indicate that Medicare has overpaid some capitated plans by 5% to 20% because selection factors resulted in enrollees with better health, on average.

To reduce financial incentives rewarding the enrollment of healthy persons and to pay more fairly for the care of frailer populations, the

BBA 1997 required Medicare to link payments to HMOs to the health status of their beneficiaries by the beginning of the year 2000. In this system, frail enrollees are eligible for higher payments than healthier cohorts are. This encouraged plans to discontinue avoiding the enrollment of more chronically ill populations and to bring a broader base of the general older adult population into managed care. In enacting Medicare Part C in 1997 to create Medicare+Choice, a new methodology was introduced to pay organizations that enter Medicare Part C contracts. The equivalent of the County Rate Book is based on the greatest of three amounts: (1) a new blended payment rate based on a calculation method combining local and national rates in setting county rates, (2) a new minimum specified rate amount, or (3) an amount that is based on a 2% increase over the prior year’s rates, with the 1997 County Rate Book serving as the baseline.

The percentage of beneficiaries enrolled in Medicare managed care increased steadily into the 1990s. Whereas only 3.6% of older Americans were enrolled in HMOs in 1990, this proportion increased to 10% in 1996 and to more than 15% in 1998. Since 2001, enrollment has been declining due to the departure of many health insurance programs from the Medicare managed care market due to reimbursement rates that are increasingly inadequate to cover medical utilization costs. The Medicare+Choice program, a major component of the BBA 1997, renamed in 2004 to Medicare Advantage, is the Medicare managed care component. It is designed to make it easier for various kinds of organizations, including PSOs and PPOs, to become participants in Medicare managed care. Medicare Advantage has been organized to encourage greater competition among health plans enrolling Medicare beneficiaries.

Managed care plans caring for Medicare recipients have applied the same paradigms to behavioral health care that they have used for their younger commercial populations. Many of these plans, perhaps a majority, “carve out” the behavioral health benefit and capitate the risk for these services to managed care organization (MCO) vendors. Most of the MCOs are large for-profit entities that function as psychiatric and substance use insurers in numerous markets regionally and nationally. MCOs generally establish local networks of ambulatory and inpatient providers; establish fee-for-service pricing with those providers; provide medical management, care management, utilization review, and credentialing functions; and pay claims. These MCO systems are generally very effective in reducing inpatient use. This effectiveness allows them to negotiate significantly discounted prices for services and to limit the size of available networks, thereby reducing the management effort required to control service use.

A review of the credentialing and procedure manuals for a group of the largest MCOs nationally found virtually no mention of requirements for specialty training or expertise in the care of older adults or for special consideration of medical comorbidity or frailty. There were no requirements for services to be sited at locations in which older adults reside or where access to care may be facilitated for frail or disabled people. This review suggests that the current model for delivery of managed behavioral health services to older adult Medicare beneficiaries is unlikely to reflect recent advances in behavioral neuroscience. Similarly, many carve-out programs exclude or limit comprehensive assessment, neuropsychological testing, and other routine components of major neurocognitive disorder evaluation.

Managed care continues to be important in Medicare policy. However, reductions in payments to managed care entities by Medicare coupled with complex paperwork requirements have prompted many managed care plans to leave the Medicare program. The 2010 Affordable Care Act provides for health care reform with additional opportunities for geriatric mental health care through ACO, patient-centered medical homes, and other structural changes in health care delivery.

Insurance Coverage Supplementing Medicare

Around 90% of older Medicare beneficiaries have supplemental Medicare coverage for service costs not covered by Medicare directly. These supplemental coverages include employer or union-sponsored retiree health plans, Medigap policies, Medicare+Choice/Medicare Advantage, and dual Medicaid–Medicare coverage.

In July 1991, Congress enacted mandatory federal Medigap standardization requirements as part of the OBRA of 1990 (OBRA-90). It provided requirements for 10 basic policies. All these policies must include payment of the Medicare Part A hospital and Part B provider coinsurances. In addition, all policies must pay any applicable 50% copayment for outpatient psychiatric services. More comprehensive policies may elect to cover deductibles, skilled nursing facility coinsurance, outpatient prescription pharmaceuticals, and preventive in-home services. Medigap regulations provide incentives for the use of PPOs by Medicare recipients. This allows insurers to offer lower premiums to members who agree to use a PPO for all their care. An increasing number of states have authorized insurers to offer this option.

The Medicare Prescription Drug, Improvement, and Modernization Act of 2003 impacts Medigap policies that have a drug benefit. People currently enrolled in a Medigap plan without a drug benefit are not affected. However, those who have a Medigap policy with drug benefits have two choices: (1) They may keep their current Medigap plan with drug benefits. However, if they later decide to enroll in a Medicare Part D plan, a late enrollment penalty may be charged if the Medigap policy is not equivalent to Medicare Part D. (2) They may enroll in a Medicare Part D plan. Those who choose to do this can either enroll in another Medigap plan without drug coverage to cover Medicare's cost-sharing for other services or keep their current Medigap plan but drop its drug benefits and pay a lower premium. People who reach the age of 65 after January 1, 2006, can enroll in Medigap policies without drug benefits. After January 1, 2006, people were unable to purchase a supplemental policy to help offset their deductibles and copayment for drug policies. Regarding employer-sponsored retiree plans, the government pays 28% of the costs that companies incur for each retiree to encourage companies to maintain their drug coverage for retirees; this amounted to between $480 and $9,850 per retiree in 2021.

On April 16, 2015, the Medicare Access and CHIP Reauthorization Act of 2015 (MACRA) was authorized. Among various actions, this replaced the Sustainable Growth Rate formula (never actually put into action due to multiple short-term Congressional “patches” since 2002). Starting in 2020, it affected insurance coverage supplementing Medicare by decreasing funding to supplemental Medicare plans, reducing “first dollar” coverage of supplemental Medigap plans so that individuals new to Medicare could not purchase Medigap plans that pay for the Part B deductible.

MEDICAID SYSTEM

Enacted in 1965 as a social insurance program to pay for the medical care of Americans with limited financial means, Medicaid is funded through a combination of federal and state matching funds. To receive these matching funds, states must provide a basic benefits package, including hospital, physician, and nursing facility services, as well as a wide range of supportive services. The program allows states to impose restrictions on the services that they fund and on the level of reimbursement. Medicaid is a means-tested and needs-based program; thus, an individual must meet certain criteria to be eligible. The eligibility varies widely from state to state, but the most important criteria are poverty and financial resources. Medicaid was expanded upon PPACA being signed into law to include all adults under the age of 65 with income up to 133% of the poverty line. Although initially a legislative requirement, mandatory Medicaid expansion was blocked by the Supreme Court of the United States (SCOTUS) in its June 2012 *National Federation of Independent Business (NFIB) v. Sebelius* decision, effectively allowing states to voluntarily participate in or decline Medicaid expansion. As of August 2021, 38 states and the District of Columbia have elected to participate.

Medicaid expansion contributed to increases in insurance coverage overall, as well as enrollment in the Medicaid program, regardless of a state’s participation status in Medicaid expansion. In states that elected to expand Medicaid, enrollment increased by 13 million beneficiaries by 2020, approximately 81.2% of whom were newly eligible individuals and entitled to the newly eligible enhanced federal matching rate. The increase in coverage observed in states that declined Medicaid expansion is likely due to a “welcome-mat” effect, in which individuals who were previously eligible but not enrolled may have subsequently elected to enroll due to the increased outreach and marketing associated with Medicaid expansion. Insurance coverage for individuals with serious psychological distress (SPD) or probable depression (PD) in Medicaid expansion states increased at an even greater rate than the general population. Medicaid expansion has been associated with increased access to health services, increased quality of medical care delivered, and reduced mortality. Initial data from 2020 to 2021 indicate that Medicaid enrollment has also increased during the COVID-19 global pandemic, during which states have been required to provide continuous coverage as a condition of increased federal funding provided under the declared public health emergency. In addition to increasing health care coverage for millions of Americans, Medicaid expansion has also reduced out-of-pocket spending on mental health services for low-income adults, particularly for adults with psychological distress (SPD). However, despite a reduction in out-of-pocket costs, Medicaid expansion does not appear to have increased the use of mental health services.

For older Americans with mental illness, Medicaid is important in two ways. First, it is the most important payer for long-term care services. The nursing home is an important site of care for older adults with severe and persistent mental illnesses, including major neurocognitive disorder, schizophrenia, and depression associated with medical illness and disability. Deinstitutionalization from state facilities shifted the financial burden of care for many people with these diagnoses from the states (in state hospitals) to cost sharing with the federal government via its partial support of Medicaid. The nursing home reform provisions of the OBRA of 1987 (OBRA-87) require preadmission screening for nursing home applicants to determine if an active psychiatric illness is present. If active treatment for an identified psychiatric disorder cannot be provided appropriately in the nursing home, alternative referral for this care is mandated. Nursing homes must demonstrate efforts to provide appropriate care for behaviorally disturbed people, and appropriate training in the management of difficult behaviors is required of all staff members of long-term care facilities participating in the Medicaid program.

Currently, Medicaid continues to be the major coverage option for long-term services and supports (LTSS). Medicaid finances approximately half of all long-term care in the United States, and nearly two-thirds of all Medicaid spending focuses on older adults and adults with disability. Medicaid's scope is broader than Medicare and encompasses services delivered in hospitals, institutions, homes, and communities. As Americans continue to age, it is estimated that over 70% of those above the age of 65 will need long-term services, and those above the age of 85 are four times more likely to need long-term services. In 2013, the most recent year with comprehensive data for both programs, 51% of the estimated cost of $310 billion for long-term services was covered by Medicaid (19% was out-of-pocket). To best manage these health system costs, state Medicaid agencies are increasingly turning to managed care to provide LTSS, resulting in more than a doubling of spending on managed long-term services and supports (MLTSS) from 2012 to 2015. As of 2017, 41 different MLTSS programs operate in 24 states, with a total enrollment of 1.8 million beneficiaries.

The second area of importance is the dual Medicare–Medicaid-eligible patients. These are individuals who not only meet the eligibility criteria for Medicare but also Medicaid (often due to financial hardship or disability). In 2020, 12.3 million Americans met this dual eligibility, and these patients account for a disproportionate amount of health care spending. The *Dual Eligible Standards* are updated annually by CMS and outline standards for dual eligibility. Even with Medicaid expansion, dual-eligible individuals do not constitute most of the Medicaid population. However, they account for over 70% of Medicaid spending. Because of this, multiple states are developing Medicare Advantage Dual-Eligible Special Needs Plans (D-SNPs), which have been shown to potentially promote more efficient health care utilization. D-SNPs are a form of Medicare Advantage plan that was authorized under the Medicare Prescription Drug, Improvement, and Modernization Act of 2003 and are specially designed to meet the needs of dual eligible beneficiaries. Approximately 3 million dual-eligible beneficiaries in 43 states and the District of Columbia were enrolled in D-SNPs as of 2021.

OUT-OF-POCKET COSTS

As discussed above, maintaining one's health is the single most expensive cost during old age. Despite governmental support in the form of Medicare and Medicaid, many older Americans bear out-of-pocket costs in health care. Part of the cost is due to the simple fact that increases in the federal budget and growth in Medicare spending have prompted political and policy interest in raising the cost-sharing obligations of older adults. Out-of-pocket costs can include the following: monthly premiums for physician services under Medicare, prescription drug coverage under Medicare, custodial long-term care services and supports, routine dental care (including dentures), routine vision care or eyeglasses, and hearing exams and aids. To cover these expenses, many opt to get supplemental insurance to cover the cost not covered or only partially covered by Medicare (e.g., Medigap, employer or union-sponsored retiree coverage, or employer-sponsored insurance for those who are still working). Those who cannot obtain supplemental insurance due to the high cost and are below the federal poverty level can receive Medicaid supplements. However, even with Medicaid expansion under PPACA, some older adults with low income do not qualify for Medicaid due to their saved assets.

Although there have been measurable reductions in recent years in per capita out-of-pocket Medicare beneficiary spending due to the growth of managed care and cost containment measures, the effects of out-of-pocket payments on older adults, particularly those with limited resources, continue to be problematic. According to the 2018 Medicare Current Beneficiary Survey, beneficiaries with traditional Medicare spent an average of $6,168 on insurance premiums and medical services, with the top quarter paying an average of $14,123. Premiums and supplemental insurance account for about 47%, and of the remaining, long-term facility costs are the highest, accounting for about 18%. This is followed by medical providers/supplies (14%), prescription drugs (11%), and dental care (6%). These out-of-pocket expenses represent a potentially significant financial burden for many households, with half of traditional Medicare beneficiaries reporting at least 16% of income being spent on out-of-pocket health care costs. The cost rises with age, and there are notable differences between men and women as they approach and pass the age of 85. For women, who pay more out-of-pocket expenses than men, the difference can be attributed to rising long-term care costs. Chronic illnesses, such as Parkinson disease, that are associated with aging have profound impacts on rising health care costs. Additionally, out-of-pocket costs can increase for those with mental illness requiring more Medicare-covered services. As discussed further in the Mental Health Parity section, coverage of mental health treatment is not equitable; hence older adults with chronic mental health issues requiring frequent or long psychiatric hospitalizations can face catastrophic costs when obtaining adequate treatment.

Since Medicare and Medicaid do not cover different levels of long-term care, privately paid long-term insurance plans are available and add to additional personal costs. Prescription drug costs continue to be the fastest-growing segment of health care costs for older Americans. To mitigate these costs, PPACA closed Medicare Part D’s “donut hole” in 2020, capping the beneficiary’s responsibility for pharmaceutical payments at 25% once they enter the coverage gap. Furthermore, PPACA restructured Medicare Part B and D premiums to reduce costs for those in low-income brackets and increase contributions from the wealthy. These measures, as well as coverage of preventative care, may work to decrease overall out-of-pocket costs.

PATIENT PROTECTION AND AFFORDABLE CARE ACT AND MENTAL HEALTH PARITY

Historically, a significant financial barrier to mental health care has been the inequality of coverage of mental treatment by insurers. While President Kennedy's administration first required the Federal Employees Health Benefits Program (FEHBP) to cover psychiatric illness at the same level as general medical care, by 1975, even FEHBP scaled back on mental health coverage. Efforts in the 1980s to improve private insurance benefits were largely driven by individual states, and no consistent parity-level care or financial coverage existed. The MHPA originated during President Clinton's administration in the context of his ultimately failed health care reform. By the time it was passed in 1996 as an amendment to the Veterans Affairs, Housing and Urban Development legislation, it just provided mental health parity for annual and lifetime dollar limits for group plans with 50 or more employees. It did not apply to annual hospitalization day or visit limits nor alcohol/substance use treatments. Most health plans found loopholes to circumvent the law, and restrictions were placed on psychiatric hospitalization days and outpatient visits. They also put a larger emphasis on cost sharing. Despite its limitations, MHPA helped push the agenda toward mental health parity. After significant work, in 2008, MHPAEA was passed to address the loopholes present in the MHPA. It underwent the implementation stage and became effective on April 5, 2010. It became applicable beginning or after July 1, 2010. MHPAEA requires that if an employer offers behavioral health coverage, it must be equal to those for general medical/surgical benefits. It continues to prohibit the use of annual and lifetime dollar limits for mental health benefits and now includes addiction benefits.

Since the passage of Medicare and Medicaid in 1965, the most significant health care reform legislation in America is the PPACA. Its overarching goals are to increase the quality and affordability of health insurance, lower uninsured rates, and reduce overall costs of health care. After its passage, it successfully underwent challenges in court on the individual mandate and federal subsidies mechanisms, most recently in 2021 when the Supreme Court upheld it for the third time. By 2016, the Department of Health and Human Services estimated that 20 million fewer Americans were without insurance, and polls indicated a decrease in the percentage of uninsured by nearly half. Most of these newly insured adults were between the ages of 18 to 64, as a high proportion of older adults were already enrolled in Medicare and, therefore, not eligible for coverage expansion. However, with changes in political support and rescinding of the federal tax penalty, the number of enrollees had gone down by 2017. Currently, 38 states and the District of Columbia have expanded coverage with Oklahoma and Missouri beginning in 2021 after voters approved ballot measures. The continued changes to PPACA continue to plague what is already a complicated healthcare landscape. With the Tax Cuts and Jobs Act of 2017, the individual mandate was repealed, and it is estimated that 13 million fewer people will have health insurance in 2027. While it is outside the scope of this chapter to give an overview of all provisions, several, as it pertains to care for older Americans, are worth noting.

For older Americans with mental illness, keeping out-of-pocket health care costs low, ensuring mental health parity, helping low-income individuals, and ensuring adequate coverage of mental health treatments are important. PPACA works on several levels to help achieve these goals. First, the law prohibits insurers from denying coverage due to pre-existing conditions and sets minimum standards for health insurance policies. As most states have set certain mental health coverage as a minimum standard at the parity level, PPACA works to ensure that mental illness treatment is adequately covered. The law also makes significant changes to the health insurance market by creating exchanges that allow individuals and employers to compare policies and prices of insurance. This exchange allows for a more affordable and robust insurance market, as do sliding scale mechanisms for low-income individuals and families (between 100% and 400% of the federal poverty level). Additionally, Medicaid eligibility has been dramatically increased. Now individuals and families with incomes up to 133% of the federal poverty level qualify. This expansion of Medicaid is arguably the single most important aspect of the law, which has worked to decrease the number of uninsured in America. Furthermore, PPACA made several important reforms to Medicare. The reimbursement model has been restructured from fee-for-service to bundled payments. This encouraged cost savings at the point of care. It also created an Independent Payment Advisory Board to help reduce costs and created several measures to monitor for and control Medicare fraud and abuse. PPACA improves preventative care coverage, which will be important to improve the lives of older adults by potentially screening for and possibly preventing chronic diseases earlier. It closed out the “donut hole” in Medicare Part D and reduced prescription costs. Mechanisms of PPACA can help serve older Americans with mental illness by improving outreach and education, improving care transitions, creating Medicare–Medicaid Coordination Office, and encouraging innovation.

The law helps to offset the cost of health care in several ways. It reduced the number of bankruptcies due to medical care costs and, in some cases, allowed individuals to maintain employment without worrying about health coverage. Innovations like medical homes, ACO, expansion of telehealth, and integrated/collaborative care models have been implemented, and their outcomes are being reviewed. Furthermore, it expanded community health centers, invested in public health programs, and promoted caregiver support. Some of these changes have been embraced by the public at large, and despite ongoing changes to the law, it is likely that significant portions of the law will continue. However, some of the existing evaluation studies do not show robust gains in every area. For example, there is evidence to suggest that while PPACA improved health care coverage overall, the incremental change to the underserved population has only been moderate. The gap between the haves and the have-nots continues to be large. The significant rise in health care coverage has increased the demand for mental health care services, yet capacity in the number of clinics, providers, and psychiatric beds has been inadequate. In some circumstances, this has led to a dramatic increase in mental health emergency room visits that can be indicative of insufficient community resources. The rapidly expanded health care coverage has also resulted in some unintended consequences. For example, to meet the demand, many states have started to embrace lower-cost mental health providers such as psychiatric mental health nurse practitioners and physician assistants.

There has been a long history of benefit inequality between mental health and general health, including higher mental health insurance premiums, limitations on mental health care coverage, and carving out mental health care from general health insurance. Importantly for older adults, the lack of mental health care parity in Medicare meant that outpatient mental health treatment services required up to a 50% copayment while general care required just 20%. This posed significant barriers for older Americans to access mental health care. With the passage of PPACA, much of the mandated parity-level coverage for mental health has been reinforced. Importantly, it also mandates that health plans that provide out-of-network coverage for medical/surgical benefits also provide equal mental health benefits. After the implementation of MHPAEA, Medicare payment liability limitations were gradually reduced, and by 2014, a 100% limitation was in effect. Thus, just like other medical treatments, mental health treatment had a cost-sharing of 20%. Unfortunately, as of this writing, the implementation of mental health parity continues to be played out on the ground level with inconsistent application across the states. Even with the passage of PPACA, there still is no specific funding or mechanism to monitor, enforce, or implement parity at the local level. This forces many psychiatrists and patients to continue advocating and working toward mental health parity. The ongoing issues related to mental health carve-out cannot be overstated. Even with Medicare and Medicaid, older adults must navigate a complex care system and often find themselves unable to get treatment at the same place as their primary care. This poses challenges to implementing care coordination, collaborative care models, and streamlined health data access. These ongoing issues prove to be a gap in care from which older adults often fall into and receive disjointed and inconsistent mental health care.

ACCOUNTABLE CARE ORGANIZATIONS AND VALUE-BASED OUTCOMES

A critical challenge in American health care can be summed up by attempts being made to achieve the Triple Aim: improving patient experience of care, improving the health of populations, and reducing the cost of health care being delivered. Recently, there have even been calls to add 4th and 5th dimensions to these goals, namely: improvements in medical health providers' well-being and implementation of health care equity into clinical care. Arguably, these are responses to the problem of rising health care costs that have not translated to positive outcomes in terms of patient experience, overall health, provider job satisfaction, and equitable care to all strata of society. When it comes to mental health care, the potential impacts of achieving these goals cannot be overstated. Overall, mental health care continues to suffer from marginalization and isolation from the rest of medicine. It is notable then that focus on mental health care can contribute significantly to a health care system to achieve these goals.

Some emerging models that will impact geriatric psychiatry in the future are ACO, integrated care, patient-centered medical homes, and population health. All these models attempt to provide cost-effective, highest-quality care–not only to the individual but to large populations. Integrated care is one response to the often disjointed and uncoordinated health care being delivered. The World Health Organization defines it as a concept that brings together inputs, delivery, management, and organization of services related to diagnosis, treatment, care, rehabilitation, and health promotion. The integration model is then designed to improve the overall access, quality, and efficiency of care delivery. One of its outcome goals is to achieve improved patient satisfaction as well. The patient-centered medical home is a model developed by PCPs where a health care provider leads a team centered on comprehensive and continuous care of an individual with the goal of maximizing health outcomes. It embraces the whole person, care coordination by a personal physician, and emphasizes quality and safety. Finally, population health focus is an approach that tries to improve large patient populations by reducing health disparities, influencing social determinants of health, and developing strategies to have specialized but hard-to-find providers focused on certain diagnoses or patient subgroups. Population health management endeavors to focus interventions on specific patients and to avoid worse outcomes in the future. By focusing specialists, like geriatric psychiatrists, on complicated patients as identified within a patient registry and/or within a large organization, it seeks to maximize the impact of the specialist. The overall result would be the identification and prevention of potentially high-cost patients.

One illustrative model for the future is mental health care in ACO and valued-based outcome models. As defined by the Centers for Medicare and Medicaid Services (CMS), an ACO is “an organization of health care practitioners that agrees to be accountable for the quality, cost, and overall care of Medicare beneficiaries who are enrolled in the traditional fee-for-service program who are assigned to it.” ACOs take on large patient populations and demonstrate lower costs to CMS compared to projected costs from usual models taking care of a similar population. The cost savings then is shared between CMS and the ACO. Conversely, if ACO shows a higher cost, it would owe the difference. Additionally, the ACOs must show performance improvements on 33 quality measures across five domains: patient/caregiver experience, care coordination, patient safety, preventative health, and at-risk population/frail older adult health. The initial demonstration programs showed $183 million in savings and improvement in clinical quality scores from 70.8% to 84%. There also has been research showing overall positive experiences from patients and providers in ACO models. After the relative success of the pioneer ACOs, PPACA established Medicare Shared Savings Program (MSSP), which is a mechanism for providers and organizations to establish ACOs, as well as different model tracks for ACOs to interact with federal agencies. As of 2015, 404 MSSP ACOs have been approved, and in the 2014 reporting period, there has been a combined $338 million in savings. Much of these savings come from a decrease in hospitalizations.

The potential benefit to ACOs in paying attention to mental health care is clear. It is now well-established that co-occurring mental illness leads to a higher degree of morbidity. Better screening and treatment of depression have been cited as critical elements in an overall improvement in health outcomes for a population. The importance of this is evidenced by the fact that depression screening and treatment are part of ACOs value outcome measures. For older populations, ACOs should be embraced. However, during its early stages of adoption, the data suggest that many psychiatric providers did not take part. Even in ACOs that had a greater focus on mental health care, the outcomes showed minimal improvements, with many citing access and provider availability as reasons for less-than-desired outcomes. Another challenging aspect of incorporating mental health care into ACOs is related to the ongoing issues of carved-out insurance, the disparity in care, and difficulties in measuring mental health outcomes. However, these are not insurmountable challenges. As part of Medicare, integrated, parity-level mental health coverage should be the standard, and advances in information systems and data-driven care can help drive quantitative outcome measures in psychiatry. Notably, because of the large scope of the problem posed by mental illnesses in older populations, it is likely that ACOs will start focusing on preventative mental health care and develop means to show improvements in provider well-being.

CURRENT AND FUTURE DIRECTIONS

Mental health care has been and will continue to be intimately related to the financial aspects of health care delivery models. As of this writing, the financial implications and impact on geriatric psychiatric care are actively evolving. PPACA and changes to traditional CMS care models have made significant changes to the insurance market (private and public), and their impact will be felt for years to come. The growth of the older adult population will continue to be a major challenge faced by health care policymakers and providers. Without continued innovation and change, older adults will continue to consume health care services at an unsustainable rate. The recent emphasis on cost reduction in service delivery, while technology advances and the size of the frail older population grows at an unprecedented rate, has created conflict, threatening stability and coherence in humanistic, scientific, and economic spheres. Advances in behavioral neuroscience and, in particular, geriatric psychiatry can improve quality of life while extending lifespans and improving the economic productivity of the fastest-growing segment of the population. Despite some concerns, there are ample opportunities for geriatric psychiatrists to get involved and take on leadership roles in ACOs, value-based care models, integrated health care systems, and data-driven care.

One significant issue that has not been adequately addressed by the ongoing legislative push to create high-quality mental health care is that of the workforce. There simply are not enough geriatric psychiatrists to take on the increases in the volume of work, and without the means to meet the demand, many insurers are turning to cheaper and more abundant provider groups like advanced practice providers. The importance of quality for our patients needs to be addressed while also dealing with the realities of our limited workforce. Additionally, the growing emphasis on quality outcome measures begs the question of how to adequately represent quality geriatric psychiatric care when chronic mental illness follows a different time course and expected outcomes. The push to integrate mental health with general health also challenges the traditional geriatric psychiatry practice model. Geriatric psychiatrists must be more transparent and collaborative with their primary care colleagues and other mental health providers. From leadership roles in ACOs to taking on the challenge of creating new models of geriatric psychiatric care, it is important that psychiatrists recognize the unique opportunities being posed in the current drive for health care parity and improved outcomes. By leveraging technologic and medical advances, geriatric mental health care is well suited to achieve these goals.

55.6 Special Areas of Interest

55.6a Psychiatric Aspects of Long-Term Care

ABHILASH K. DESAI, M.D., AND GEORGE T. GROSSBERG, M.D.

The prevention and treatment of psychiatric disorders is a critical component of comprehensive, state-of-the-science care for all individuals who live in long-term care (LTC) homes. More than 90% of the LTC population, at some point, will experience clinically significant psychiatric symptoms. Table 55.6a–1 shows the prevalence of common psychiatric disorders in the LTC population. Thus, psychiatric care is a core component of the day-to-day care of most residents in long-term care facilities (LTCFs).

Table 55.6a–1.

Prevalence of Common Psychiatric Disorders in Long-Term Care

Psychiatric Syndrome (Point Prevalence)	Key Example(s)	Comments
Major neurocognitive disorders (MNCD) (60%–90%)	Alzheimer disease (AD) Vascular cognitive impairment (VCI) Parkinson disease dementia Dementia with Lewy bodies Frontotemporal dementia Traumatic brain injury and chronic traumatic encephalopathy Hypoxic/Anoxic encephalopathy Alcohol-related dementia Long COVID-19	Many residents have both AD and VCI. Most residents are in advanced stages of major neurocognitive disorder. Behavioral and psychological symptoms of major neurocognitive disorder are the most common reason for psychiatric consultation. Many residents, especially in subacute care, have mild neurocognitive disorder and, when there is superimposed depression or delirium, may be misdiagnosed as having major neurocognitive disorder.
Depressive disorders (20%–40%)	Depression due to MNCD, stroke,	Adequate control of pain is needed to

	cerebrovascular disease, or another general medical condition (most common) Major depression (single episode and recurrent) Persistent depressive disorder Adjustment disorder with depressed mood or with mixed depression and anxiety Depression due to medications	improve depression, and optimal treatment of depression is needed to improve pain for residents who have pain and depression. Drug–drug interactions between antidepressants (e.g., SSRIs) and drugs used to treat medical comorbidity (e.g., tramadol, diuretics, warfarin) are common and need to be monitored. A schedule of pleasant events and physical exercise have been found to be effective in the treatment of depression in residents with MNCD.
Delirium (5%–15%)	Hypoactive delirium (most common) Hyperactive delirium Mixed delirium	Delirium is especially prevalent among residents newly transferred from an acute care hospital (subacute settings

		in skilled nursing facilities). Subsyndromal delirium is even more common and commonly manifests with new onset of agitation and/or new onset of falls. Delirium is often the only initial manifestation of COVID-19 in the LTC population.
Psychotic disorders (5%–10%)	Psychotic symptoms due to MNCD (most common) Psychotic symptoms due to Parkinson disease and dopaminergic agents used to treat Parkinson disease Schizophrenia and schizoaffective disorder	Psychotic symptoms are also common in the context of delirium. Psychotic symptoms are a common cause of persistent physical aggression. As adults with schizophrenia live longer, their prevalence in LTC is expected to rise further.
Hypomania and mania (2%–5%)	Bipolar disorder (types I and II) (most common)	As adults who have bipolar disorder live longer, their prevalence in LTC is

	Medication-induced hypomania or mania Hypomania or mania due to stroke or another general medical condition	expected to rise further. Corticosteroids are the most common cause of medication-induced hypomania or mania.
Anxiety disorders (lack of rigorous data on prevalence; our clinical experience suggests high prevalence)	Anxiety symptoms and bathing phobia in the context of major neurocognitive disorder (most common) Generalized anxiety disorder Panic disorder Fear of falling	Anxiety symptoms are often comorbid with depressive symptoms. Premorbid subsyndromal generalized anxiety disorder is often exacerbated by the development of an MNCD.
Trauma-related disorders (lack of rigorous data on prevalence; our clinical experience suggests growing prevalence)	Posttraumatic stress disorder (PTSD) Nightmare disorder Subsyndromal PTSD	War veterans, victims of abuse (physical, sexual, emotional), and victims of a motor vehicle accident should be identified at the time of admission to an LTCF so that investigation for the presence of PTSD can be done soon after admission.
Impulse-control disorders (5%–	Sexually inappropriate	Dopamine agonists (pramipexole,

15%)	behaviors in the context of MNCD (especially VCI)	ropinirole, rotigotine) may cause impulse-control problems, including sexually inappropriate behaviors and excessive gambling or spending sprees.
Substance-use disorders (lack of rigorous data on prevalence; clinical experience indicates growing and significant prevalence)	Alcohol (most common) Tobacco Prescription opioids Benzodiazepines Cannabis Caffeine	Hazardous use of alcohol, tobacco, prescription opioids, and benzodiazepines that do not meet the criteria for a substance use disorder is prevalent in long-term care and should be treated vigorously. As more baby boomers enter LTC, the prevalence of substance-use disorders (especially alcohol and marijuana) in the LTC population is expected to grow.
Other psychiatric disorders with a growing prevalence	Disorders of the sleep–wake cycle Eating disorders Intellectual disability	These disorders are often comorbid with other psychiatric disorders. They need to be identified

	Autism spectrum disorder Personality disorder	and the treatment plan modified accordingly.

SSRIs, selective serotonin reuptake inhibitors.

APPROACH TO EVALUATING AND MANAGING PSYCHIATRIC SYMPTOMS AND DISORDERS

A systematic approach to evaluating and managing psychiatric disorders using evidence-based practices and interventions has the potential to reduce suffering dramatically and prevent unnecessary visits to the emergency department and hospitalization. Table 55.6a–2 lists the role of psychiatric consultant (psychiatrist, psychiatric nurse practitioner, psychiatric physician assistant) in LTC. The authors recommend four steps to evaluate and manage psychiatric disorders in the LTC population.

Assessment of Safety

The first step is to assess safety. The psychiatric consultant may need to address behaviors that pose an imminent danger to the resident or others (behavioral emergencies), such as violent or suicidal behaviors, before attempting to assess underlying psychiatric problems. Suicidal behaviors can be direct (e.g., suicidal ideas, such as voicing thoughts to cut oneself with a knife or scissors, or suicide attempts, such as attempting to strangle oneself with a cord) or indirect (e.g., refusing dialysis, refusing food, or life-preserving medications such as warfarin). Completed suicides, although rare in LTC, may be more common than in the community. Psychopharmacological medications (PPMs) may need to be used judiciously to address behavioral emergencies. Table 55.6a–3 lists PPMs that are commonly used to manage behavioral emergencies. If a behavioral emergency cannot be resolved, the resident may need to go to the nearest emergency department for urgent evaluation and stabilization.

Team-Based Evaluation to Identify Causes of Psychiatric Symptoms and Disorders

The second step is for a multidisciplinary team (resident, family members, primary care provider, psychiatric consultant, nurse, nursing assistant, social worker, and activity therapist) to identify all factors that may contribute to psychiatric symptoms. Psychiatric symptoms are typically due to several specific reversible or modifiable causes. Table 55.6a–4 lists common reversible causes of psychiatric symptoms in the LTC population. Obtaining the resident's perspective is essential, even if the resident has significant cognitive impairment. Diagnoses listed in the LTC resident record need to be validated as they are often incorrect. In complicated cases (e.g., presence of chronic mental illness, refractory and severe behavioral and psychological symptoms of neurocognitive disorder, concerns of abuse and neglect, complex polypharmacy), the psychiatric consultant may need to consult a professional who has geriatric expertise (e.g., geriatric psychiatrist). Telepsychiatry may improve access to geriatric psychiatrists who may be able to be present via audio/video to assess the resident along with the primary care provider.

Action Plan

In the third step, the team collaboratively devises and institutes an action plan (treatment plan) that is individualized and directed at the specific target psychiatric symptoms, diagnoses, and differential diagnoses identified in the second step. An action plan generally consists of a multimodal approach combining a variety of psychosocial environmental interventions targeted at caregivers and residents to address psychiatric symptoms that are most distressing or problematic. An action plan should address all the potentially modifiable causes of psychiatric symptoms identified during the evaluation. Professionals from allied fields (e.g., recreational therapist, dietician, psychologist, pharmacist, occupational therapist, physical therapist, speech therapist, music therapist, art therapist, board-certified behavior analyst) and professionals who have knowledge of complementary and alternative medicine (e.g., aromatherapy, massage therapy, horticultural therapy) can play valuable roles, especially in complicated and or treatment-resistant cases. PPMs may be the first line in behavioral emergencies related to violent behaviors, relapse of pre-existing psychiatric disorder (e.g., bipolar disorder), new onset of major depression, persistent and distressing psychotic symptoms, and persistent aggressive behavior. Table 55.6a–5 lists key principles of psychopharmacology with the LTC population.

Response to Treatment

The fourth step involves appropriately monitoring the adverse effects of interventions as well as response to treatment so that the psychiatric consultant can evaluate whether to modify or continue the interventions. If the problem is not improving, the psychiatric consultant should discontinue the intervention. If the intervention included an antipsychotic for the management of severe persistent aggression in residents with advanced dementia, the psychiatric consultant should make systematic attempts to taper the dosage and discontinue the medication after 4 to 7 months.

DELIRIUM AND PSYCHIATRIC ASPECTS OF COMORBID MEDICAL CONDITIONS

Age above 85, presence of a neurocognitive disorder, and polypharmacy are the three most important risk factors for delirium in the LTC population. Residents who have advanced stages of Major Neurocognitive Disorder (MNCD) have low cognitive reserve and thus are prone to develop delirium even with mild conditions such as urinary tract infection or a new medication that has anticholinergic activity. The psychiatric consultant should consider an acute change in mental status the sixth vital sign (pain being the fifth vital sign and heart rate, respiratory rate, temperature, and blood pressure being the first four vital signs). New onset of falls and agitation are the two most common early signs of developing delirium in LTC populations.

New onset of agitation is one of the most common reasons for psychiatric consultation, and the psychiatric consultant may be the first health care professional to diagnose delirium.

There are three types of delirium: hypoactive (most common), hyperactive, and mixed. Psychotic symptoms are common during delirium and may cause the resident to become severely agitated or physically aggressive, further complicating management. The Confusion Assessment Method (CAM) is a useful tool for improving the accurate diagnosis of delirium in the LTC population. Table 55.6a–6 lists common causes of delirium in the LTC population. Mania can also mimic delirium. Management of delirium involves ensuring safety and identifying and treating its various causes. Judicious short-term use of low doses of atypical antipsychotics or haloperidol may be appropriate and necessary for the management of severe physical aggression and psychotic symptoms in the context of delirium.

Table 55.6a–2.
Role of the Psychiatric Consultant in Long-term Care Homes

Areas of Concern	**Role of the Psychiatric Consultant**
Medicalization of human suffering (e.g., antidepressant given for adjustment disorder with depression)	Normalize distress related to losses and adjusting to living in an institution; deprescribe psychiatric medications given for adjustment problems
Inappropriate treatment of behavioral emergencies (e.g., suicidal ideas, aggression)	Guide PCP and team in prompt assessment, understanding the behavioral emergency and appropriate treatment
Inaccurate psychiatric diagnoses (e.g., dementia-related psychoses diagnosed as schizophrenia)	Conduct a comprehensive psychiatric evaluation and provide accurate diagnoses
Irrational psychopharmacologic medication use (e.g., quetiapine used for insomnia)	Rational psychopharmacologic medication use
Medication-induced psychiatric problems (e.g., anticholinergic medications causing cognitive impairment)	Identify medications that could be contributing to or causing psychiatric problems and, in collaboration with PCP and consultant pharmacist, institute appropriate interventions (e.g., rational deprescribing of anticholinergics)
Under-recognition of medical conditions causing agitation in persons with MNCD	Help PCP identify potential medical conditions (e.g., infection, delirium, pain) that may be causing or worsening agitation in persons with MNCD
Inadequate optimization of	Work with family and staff to

psychosocial environmental approaches to manage agitation in persons with MCND	problem solve, provide education, and optimize personalized strengths-based psychosocial environmental approaches to effectively reduce distress in persons with MNCD
Low utilization of individual and group counseling for psychiatric disorders (e.g., depression, chronic pain, chronic insomnia, chronic anxiety)	Help the team identify residents who could benefit from individual and group counseling (e.g., cognitive-behavioral therapy)
Delayed recognition of the need for hospice and palliative care in residents with advanced dementia	Help the team recognize the need for hospice and palliative care in residents with advanced dementia
Lack of knowledge and skills to manage “difficult” residents (e.g., residents with trauma, personality disorders, and addictions)	Staff and family education, guidance, and support in appropriate management of trauma, personality disorders, and addictions
PCP needs help assessing the resident’s capacity to make medical decisions	Psychiatrists can assess resident’s decision-making capacity and guide the PCP and team

Table 55.6a–3.
Guide to Key Psychopharmacological Options for Management of Acute Agitation in LTC[a]

Psychopharmacological Options (Including Dosages per 24 Hours, Routes of Administration)*b*	**Common Conditions**	**Clinical Pearls**
Haloperidol (0.5 mg–2 mg; tablet, liquid, intramuscular injection)	Delirium Acute exacerbation of chronic mental illness (e.g., Schizophrenia, Bipolar Mania)	Drug of choice in delirium (while causes are being investigated) Avoid in residents with pre-existing parkinsonism or a history of extrapyramidal syndrome (EPS) due to antipsychotics
Risperidone (0.5–2 mg; tablets, liquid, orally disintegrating tablet [ODT])	Delirium Acute exacerbation of chronic mental illness (e.g., Schizophrenia, Bipolar Mania)	Avoid in residents with pre-existing parkinsonism or a history of EPS due to antipsychotics
Olanzapine (5–10 mg; tablet, ODT) (2.5–5 mg intramuscular injection)	Delirium Acute exacerbation of chronic mental illness (e.g., Schizophrenia, Bipolar Mania)	Avoid in residents at high risk of anticholinergic toxicity (e.g., residents with high pre-existing anticholinergic burden, residents with urinary retention)
Ziprasidone (10–20 mg;	Delirium	Avoid in residents

intramuscular injection)	Acute exacerbation of chronic mental illness (e.g., Schizophrenia, Bipolar Mania)	with prolonged QTc interval (especially if QTC is longer than 500 msec)
Aripiprazole (5–10 mg; ODT) (9.75 mg intramuscular)	Delirium Acute exacerbation of chronic mental illness (e.g., Schizophrenia, Bipolar Mania)	Monitor for akathisia
Asenapine (5–10 mg; sublingual)	Delirium Acute exacerbation of chronic mental illness (e.g., Schizophrenia, Bipolar Mania)	Cost may be a barrier to its use
Chlorpromazine (25–50 mg; tablets) (10–25 mg intramuscular injection)	Delirium Acute exacerbation of chronic mental illness (e.g., Schizophrenia, Bipolar Mania)	Used if other options are not feasible or not effective Monitor for hypotension
Lorazepam (0.5–5 mg; tablet, liquid, intramuscular injection)	Delirium related to alcohol withdrawal or benzodiazepine withdrawal Panic attack Acute exacerbation of chronic mental illness (e.g., Schizophrenia, Bipolar Mania)	Avoid in residents with advanced lung disorders In some situations (e.g., acute exacerbation of schizophrenia), a combination of lorazepam and haloperidol or lorazepam and

		risperidone may be considered
Midazolam (10–20 mg; liquid; higher doses as subcutaneous infusion may be needed in some situations)	Palliative sedation for refractory agitation during end-of-life care	Training in the use of buccal midazolam is needed. Buccal midazolam is generally used for the management of seizures as an alternative to rectal diazepam

---

[a] Identification and treatment of underlying causes and nonpharmacologic interventions (e.g., de-escalation strategies) are always first-line interventions. No medication has been approved by the FDA for the management of delirium. Intramuscular olanzapine, ziprasidone, and aripiprazole have been approved by the FDA for the management of acute agitation in patients with schizophrenia, but they have not been studied in LTC populations. Start with lower dosages and may repeat the dose in 30–45 minutes if the initial dose is not effective.

[b] In frail elderly, dosages may need to be lower, and for some elderly (e.g., young-old [age 65–75 years] who are not frail), dosages may need to be higher than suggested here. Oral routes of administration are preferred over parenteral; ODT, liquid, and sublingual are preferred over tablets.

Table 55.6a–4.

Common Reversible Causes of Psychiatric Symptoms in Long-Term Care

Cause	Key Example(s)	Potential Psychiatric Symptoms
Medications	Benzodiazepines Anticholinergics Corticosteroids Dopamine agonists Opioids	Cognitive impairment Agitation Hypomania, mania Psychotic symptoms Impulse control disorders
Physical health conditions	Adverse drug events, pain, neuropathy, constipation, urinary tract infection, dehydration, delirium, anemia, hypoglycemia, vitamin B_{12} deficiency, vitamin D deficiency, low blood pressure due to overtreatment of hypertension, allergies, dry skin	Agitation Depression Cognitive impairment
Sensory deficits	Hearing deficit Vision deficit	Depression Agitation Paranoia Visual hallucinations Cognitive impairment
Disorders of the sleep–wake cycle	Insomnia Obstructive sleep apnea	Increased or decreased sleep Night-time agitation Cognitive impairment

	Excessive daytime sleepiness REM sleep behavior disorder Restless leg syndrome	
Psychiatric conditions	Major neurocognitive disorders Major depression (single episode or recurrent) Generalized anxiety disorder Post-traumatic stress disorder (PTSD) Bipolar disorder Schizophrenia	Agitation/aggression Social withdrawal Insomnia Cognitive impairment Nightmares Poor food and fluid intake Delusions Hallucinations Hypomania/mania
Long-term care staff approach	Impatience Lack of empathy Over expectation	Agitation/aggression Depression Anxiety
Long-term care staff's understanding of psychiatric symptoms/disorders	Staff's lack of understanding of aging-related disability ("he can stay in bed all day, as he is 90 years old and is tired")	Agitation Depression Insomnia
Long-term care staff distress	Caregiver anxiety and depression Caregiver burnout Excessive caregiver burden (having to	Agitation Depression

	care for too many residents)	
Negative environmental factors	Nighttime noise Low lighting Boredom Overstimulation Improper or inadequate incontinence care routines Therapeutic diet Lack of places to wander safely Physical restraint	Agitation Depression Anxiety Poor food and fluid intake Insomnia
Unmet needs of residents	COVID-19 and pandemic-related restrictions Toileting, hunger Physical activity Spend time with nature To be productive, to be needed Spiritual needs To express and vent Freedom from restraint	Loneliness Agitation Depression Anxiety

Case example 1: Ms. A is a 65-year-old woman who recently transferred from a local hospital to a skilled nursing facility. She was referred for psychiatric evaluation because she was not eating, appeared depressed, and was not sleeping well. The nursing staff suspected depression. During the assessment, the psychiatric consultant discovered that Ms. A had undergone a colonic resection for ulcerative colitis and had excessive liquid drainage from an ileostomy. During the examination, Ms. A was inattentive and somewhat drowsy, and had psychomotor retardation. The psychiatric consultant diagnosed hypoactive delirium, possibly due to disorders of fluids and electrolytes. A subsequent basic metabolic panel showed hyponatremia, elevated blood urea nitrogen, and serum creatinine (higher than baseline), confirming the diagnosis. Treatment with intravenous fluids at the facility quickly brought resolution of the presenting symptoms.

Clinical pearl: Hypoactive delirium often presents as depression.

Table 55.6a–5.
Key Principles of Psychopharmacology in Long-term Care

1. Prescription of even a single psychopharmacologic agent is a complex decision. It should be undertaken judiciously and, in most situations, after psychosocial environmental interventions have been tried and failed.
2. Start low, go slow, and keep going. Initial doses of psychotropic drugs need to be low or, for frail residents, very low. The dose increase needs to be slower than for younger adults. Final therapeutic doses for some residents may need to be as high as those for younger adults.
3. The benefit–risk ratio for all pharmacologic agents (including psychopharmacologic drugs) is lower than that for younger adults, necessitating close monitoring for adverse effects and prompt discontinuation of the drug if adverse effects develop or if there is no therapeutic response.
4. The psychiatric consultant should evaluate for periodic dose reduction and discontinuation of psychotropic drugs, and documentation should include the justification for continued use of psychopharmacologic agent(s).
5. The psychiatric consultant should promptly reassess the benefit-risk ratio of all psychotropic drugs whenever there is a significant decline in the resident’s overall health and functioning or a decline in renal and/or hepatic function.
6. Psychopharmacologic therapies should comply with regulatory guidelines for the use of medications in nursing homes.
7. The psychiatric consultant should provide residents and their surrogate decision makers optimal information regarding the risks and benefits of psychopharmacologic therapies and alternatives before initiating therapy and periodically thereafter.

Malnutrition

Malnutrition is prevalent in the LTC population. It commonly manifests as unintentional weight loss or, less commonly, as excessive weight gain and is a common reason for psychiatric consultation. Weight loss is usually accompanied by loss of appetite (including general loss of appetite as well as loss of appetite for food offered at the facility) or refusal of food. Depression is one of the most common causes of a general loss of appetite. Medications such as cholinesterase inhibitors also can cause anorexia and weight loss. Not having someone available to assist with meals, especially in residents with MNCD, is also a common reason for weight loss in the LTC population. Liberalizing diets, increasing assistance during feeding, optimizing dental health, cutting food into smaller and manageable sizes (finger foods), giving smaller portions at each meal, and increasing the availability of favored snacks throughout the day can help address the problem of food refusal. The psychiatric consultant should evaluate all residents who refuse food for depression as well as for psychotic symptoms (especially delusions of food being poisoned). For residents who have depression accompanied by loss of appetite and weight loss, the psychiatric consultant may consider prescribing mirtazapine as the first choice antidepressant. Nutritional supplements should be given between meals rather than with meals.

The prevalence of obesity and excessive weight gain is increasing in the LTC population. This is typically accompanied by excessive consumption of calorie-dense food. Along with a sedentary lifestyle, PPMs (e.g., valproate, olanzapine, quetiapine) and other pharmacologic medications (e.g., gabapentin) are common causes of excessive weight gain. It may be necessary to discontinue PPMs that are thought to cause or contribute to weight gain and, as necessary, replace them with alternative PPMs that have a lower propensity for weight gain.

Table 55.6a–6.
Common Causes of Delirium in Long-Term Care

Cause	Key Example(s)	Comments
D: Drugs	Anticholinergic drugs Benzodiazepines Opioids Steroids	Drugs listed in the Beers list of drugs that are inappropriate for older adults often cause cognitive impairment and delirium. Many drugs have low anticholinergic activity and, if used with other drugs that have anticholinergic activity, may increase anticholinergic load sufficient to cause delirium. Benzodiazepine withdrawal can cause delirium.
E: Embolic—thrombotic	Pulmonary emboli Deep vein thrombosis (DVT) Cerebrovascular accident (CVA) COVID-19	Residents who spend a large amount of time in bed (e.g., those who have depression or those who are in pain) are at high risk of DVT and its complications. Neuroimaging may be necessary to diagnose CVA accurately.
L: Last phase of life	Residents in an end-of-life state	Delirium is common in the terminal stages of major neurocognitive disorder.
I: Infections	Urinary tract infection	Asymptomatic bacteriuria and asymptomatic

	Bronchitis Pneumonia Cellulitis COVID-19	pyuria are prevalent, especially among women, and often misdiagnosed as urinary tract infections. Delirium may be a more common manifestation of pneumonia than fever and cough.
R: Respiratory conditions R: Renal conditions	Acute exacerbation of chronic obstructive pulmonary disease (COPD) Acute renal failure (ARF)	Acute bronchitis is one of the common causes of exacerbation of COPD. Dehydration is a common cause of ARF.
I: Intestinal conditions I: Injury	Acute intestinal obstruction, including fecal impaction Hip fracture Head injury	Inadequate treatment of constipation often leads to intestinal obstruction.
U: Urologic	Urinary retention	Drugs that have anticholinergic activity are the most common cause of acute urinary retention.
M: Myocardial dysfunction M: Metabolic	Acute myocardial infarction (AMI) Dehydration Hypothyroidism or hyperthyroidism Hyponatremia	Delirium may be a more common manifestation of AMI than chest discomfort. Laboratory tests may be the only way to

	diagnose dehydration accurately.

Macro- and micronutrient deficiencies can often lead to depression, insomnia, and neurocognitive disorders. Many commonly used medications can cause micronutrient deficiencies (e.g., metformin and proton pump inhibitors are associated with vitamin B12 and magnesium deficiency). Checking vitamin levels (e.g., B12, D, B1), magnesium levels, and tests for celiac disease may be necessary in some cases. Vitamin supplementation without checking for blood levels may improve mental health outcomes.

Dieticians may be consulted to address nutritional deficiencies but also for education related to dietary strategies for boosting brain function (e.g., Mediterranean diet, MIND diet) and for drug–food interactions (e.g., dietary needs of individuals on lithium).

Many psychiatric medications need to be taken with food for adequate absorption (e.g., ziprasidone needs to be taken on 500 calories meal, lurasidone needs to be taken on 350 calories meal), and some psychiatric medications should not be taken with meals (e.g., quetiapine extended release).

Chronic Pain

Psychiatric consultation can provide valuable help in improving outcomes and the quality of life of residents who are experiencing chronic pain. Depression is common, underrecognized, and undertreated in residents who have chronic pain. Pain is one of the most common causes of agitation in residents who have MNCD, especially verbal agitation (e.g., yelling, screaming, verbally abusive behavior) and resisting personal care. The psychiatric consultant should consider pain the fifth vital sign. We recommend the *ATMAN* approach for the management of chronic noncancer pain without opioids and tramadol. Refer to Table 55.6a–7 for the description of the *ATMAN* approach. This involves the use of topical analgesics and nondrug interventions as first line, nonopioid oral analgesics, and interventional pain management as second line, and only in intractable cases, the use of tramadol or other opioids. Antidepressants, especially serotonin-norepinephrine reuptake inhibitors (SNRIs, such as duloxetine), can help reduce the perception of pain and improve function as well as the quality of life, even in the absence of significant depression, for residents who have chronic pain. Serious adverse drug–drug interactions between psychotropic drugs and analgesics (e.g., selective serotonin reuptake inhibitors [SSRIs] and tramadol [increased risk of seizure and serotonin syndrome], benzodiazepines and opioids [increased risk of delirium, falls, and injury]) can be prevalent and underrecognized in the LTC population. The psychiatric consultant should consider recommending a trial of scheduled acetaminophen to treat agitation (especially verbal agitation) in individuals with advanced MNCD before prescribing PPM. Psychiatric care should be a key component of an integrated approach to chronic pain management.

Table 55.6a–7.
ATMAN Approach to Managing Chronic Noncancer Pain Without Opioids and Tramadol

A:	Acetaminophen, Antidepressants (especially selective serotonin-norepinephrine reuptake inhibitors)
T:	Topical agents (e.g., diclofenac, lidocaine, capsaicin)
M:	Muscle relaxants (e.g., baclofen, baclofen pump)
A:	Anti-inflammatory agents (e.g., NSAIDs, intra-articular glucocorticoids), anticonvulsants (e.g., gabapentin, pregabalin, carbamazepine)
N:	Nondrug interventions (e.g., cognitive-behavioral therapy for pain, exercise, multimodal rehabilitation, physical therapy, self-management, heat, and cold remedies)

SPECIFIC DISORDERS AND LONG-TERM CARE

Major Neurocognitive Disorders (Dementias)

Evaluation and treatment of MNCDs are key aspects of psychiatric care for LTC residents. Residents who have MNCD and have not had a thorough evaluation to clarify its cause(s) may need workup to rule out potentially treatable or reversible factors of cognitive decline, including thyroid dysfunction, vitamin deficiency (e.g., B12 deficiency), subdural hematoma, normal pressure hydrocephalus, central nervous system infection, and brain tumor. The authors recommend using the Montreal Cognitive Assessment (MoCA) or Saint Louis University Mental Status (SLUMS) to assess residents' cognitive function. The Brief Mental Status Interview is not as thorough as the previous two scales, although it is part of the Minimum Data Set used to assess all residents in nursing homes in the United States.

Behavioral and psychological symptoms of MNCD (also called behavioral and psychological symptoms of dementia [BPSD]) are one of the most common reasons for psychiatric consultation. They are a heterogeneous group of symptoms that tend to cluster into five distinct groups—depression, apathy, psychotic symptoms (delusions and hallucinations), sleep disturbance, and agitation—and are distinct from the cognitive deficits that are the hallmarks of all MNCD. Agitation, defined as "inappropriate verbal, vocal, or motor activity that is not explained by needs or confusion per se," can be characterized as either aggressive or nonaggressive. Aggressive behaviors can occur with or without agitation and include fighting, throwing, grabbing, destroying furniture, cursing, and screaming, whereas nonaggressive agitated behaviors include restlessness, pacing, wandering, hoarding, repetitive questioning, inappropriate disrobing, and verbal outbursts. Agitation is best understood as an expression of a resident's efforts to communicate unmet needs. The majority of individuals who have MNCD (including those who have advanced MNCD) can speak for themselves to a much higher degree than has been recognized to date. The psychiatric consultant should make all efforts to understand the resident's perspective and have the treatment plan guided by that perspective. The psychiatric consultant may use the Agitation Subscale of the Neuropsychiatric Inventory nursing home version, Cohen Mansfield Agitation Inventory, or Pittsburgh Agitation Scale to evaluate the severity of agitation and to document response to treatment. The impact of the COVID-19 pandemic is disproportionately high on individuals with advanced dementia. Tables 55.6a–8 and 55.6a–9 describe the impact and potential psychosocial interventions to mitigate stress and address complications.

Management of MNCD should begin with a discussion with the resident and/or their family regarding the potential benefits of using cholinesterase inhibitors and memantine. Some more-capable residents (e.g., residents who have mild neurocognitive disorder due to probable Alzheimer type and highly motivated residents who have mild MNCD) may benefit from and often prefer interventions to slow cognitive decline. For these residents, creating and implementing an individualized brain fitness program that includes regular exercise, a MIND diet, and cognitive and social strategies in various combinations is appropriate and recommended.

Individualized, strengths-based psychosocial environmental interventions (also called nonpharmacologic interventions) are recommended as the first line of treatment for all behavioral and psychological symptoms related to MNCD because they are effective (at least modestly) and the risks are minor. Table 55.6a–10 lists psychosocial environmental interventions for neurocognitive disorder, and Table 55.6a–11 lists key staff training programs.

Table 55.6a–8.
Impact of COVID on Residents With Dementia

Stressor	Potential Biologic–Psychosocial Mechanisms	Potential Negative Consequences
Physical distancing, masks, lockdown, and other infection-prevention interventions	Loneliness Difficult understanding spoken and nonverbal facial communication Trauma	Depression Apathy Agitation Anxiety
Acute COVID infection	Elevated cytokines Hypoxia Ischemia and blood clots Adverse effects of medications used to manage COVID (e.g., dexamethasone)	Delirium Fatigue Psychosis (rare) Agitation Increased mortality
Post-COVID sequelae (Long COVID)	Persistent inflammation in cerebral blood vessels Loss of taste	Persistent neurocognitive impairment (“Brain Fog”) Reduced food intake and weight loss

The psychiatric consultant should institute PPMs to treat severe and persistent agitation related to MNCD only after thoroughly evaluating and treating all potentially treatable medical conditions and other modifiable factors, and psychosocial environmental interventions have not been adequate in addressing them.

Discussions should make it clear that any psychopharmacologic intervention for agitation in the context of neurocognitive disorder is off-label (i.e., is not approved by the U.S. Food and Drug Administration for its treatment) with the exception of suvorexant, that is approved by the U.S. FDA for insomnia due to Alzheimer's disease dementia and brexpiprazole, that is approved by the U.S. FDA for the treatment of agitation due to Alzheimer's disease dementia.

Antipsychotics are one of the most commonly prescribed PPMs for the treatment of agitation and aggression among residents who have MNCD, and the prevalence of use in the LTC population is high (20% to 25%). There is a strong initiative from the Center for Medicare and Medicaid Services (CMS) in the United States to reduce the use of antipsychotics in the LTC population. In addition, the United States Congress has passed legislation mandating the reduction of antipsychotic use in nursing homes. This is in response to strong evidence that antipsychotics are often used inappropriately in the LTC population (the majority of its use is by residents who have MNCD), and the use of antipsychotics by individuals who have MNCD carries high risks of morbidity (e.g., cerebrovascular event, pneumonia, deep vein thrombosis, hip/femur fracture) and increased mortality. Table 55.6a–12 shows a stepped-care approach to the appropriate use of antipsychotic medications for MNCD. The psychiatric consultant may consider prescribing short-term use of low-dose brexpiprazole, risperidone, olanzapine, quetiapine, and aripiprazole to treat severe agitation, aggression, and psychosis with dementia in certain clinical situations (e.g., clear risk of harm to the resident or others and psychosocial environmental interventions have not been effective). Risperidone is approved for short-term use (up to 6 weeks) to manage severe aggression in individuals with MNCD in Europe. Atypical antipsychotics are preferred over conventional antipsychotics (e.g., haloperidol), which are associated with higher risks. High-potency antipsychotics (e.g., risperidone, haloperidol) should be avoided in individuals with parkinsonism (e.g., Parkinson disease (PD), Lewy Body Dementia). It is important that the psychiatric consultant explain to the surrogate decision maker(s) that severe psychotic symptoms and/or persistent aggression are associated with considerable emotional distress, increased mortality, falls, and hospitalization; hence, in certain situations, the use of antipsychotics may be justified. To minimize risks, the authors recommend prescribing the lowest possible dose of antipsychotics for the shortest possible time and regular monitoring of metabolic parameters when appropriate and for extrapyramidal symptoms.

Table 55.6a–9.
Examples of Some Innovative Psychosocial Interventions to Address Loneliness and Trauma

1. Small-group activities (including opportunities for exercise)
2. Distanced-communal dining
3. Compassionate care visits
4. Window visits with family and friends
5. Video visits with family and friends (Facetime, Skype, Zoom, and other platforms)
6. Reading books, poems, scriptures
7. Audiobooks
8. Music-based interventions (including personalized music on an MP3 player or iPod)
9. Encouraging residents to apply lavender (or another soothing scent) lotions to hands, feet, and neck
10. Simulated presence therapy: playing select audio–video recordings of family and friends
11. One-to-one interaction (includes supervised visits outdoors to look at squirrels and birds).

Among mood stabilizers, there is some support for the use of carbamazepine to treat physical aggression in MNCD, but its use carries considerable risks, including falls, drug–drug interaction, and delirium. Valproate has been the most studied of all anticonvulsants for the treatment of behavioral and psychological symptoms of MNCD, but the results to date have been inconsistent or negative, and its use carries considerable risks (especially falls and sedation).

Hence, the authors do not recommend the use of valproate to treat behavioral and psychological symptoms of MNCD.

SSRIs (especially citalopram and escitalopram) and low-dose trazodone are options for the treatment of persistent anxiety, irritability, agitation, and aggression not responding to psychosocial environmental interventions. The psychiatric consultant may also consider prescribing antidepressants to treat severe emotional lability. Antidepressants, although safer than antipsychotics, carry considerable risks, including the risk of increased agitation, nausea, insomnia, hyponatremia, bleeding (especially if used concomitantly with anticoagulants), and falls. Some antidepressants (e.g., duloxetine) also pose a risk of orthostatic hypotension. The psychiatric consultant may consider prescribing a trial of a combination of dextromethorphan and quinidine to treat pseudobulbar affect. The psychiatric consultant may consider a judicious trial of methylphenidate for residents who have MNCD or traumatic brain injury and are experiencing severe apathy when psychosocial environmental interventions have not been effective, and there are no cardiac contraindications. The use of benzodiazepines carries a high risk of serious adverse effects (especially delirium, falls, and injury) and thus should be minimized. Short-term use of low-dose short-acting benzodiazepines such as (lorazepam or oxazepam) is an option for the treatment of prominent anxiety or infrequent severe agitation. Hydroxyzine carries a significant anticholinergic effect, and hence its use to treat anxiety in individuals with MNCD should be avoided.

Table 55.6a–10. Psychosocial/Environmental Interventions for Neurocognitive Disorders

Psychosocial Interventions Directed Toward Caregivers

Type of Psychosocial Environmental Intervention	Examples	Practical Suggestions
Staff education	Education about dementia Education about Parkinson disease Education about common triggers for agitation Education about adverse psychiatric effects of commonly prescribed medications	Case-based education is preferred. Recording the education and making it available on a website for caregivers to review on their own time. Providing work credit for caregivers who complete the education.
Staff training	Training in approach to the management of behavioral and psychological problems in long-term care residents Training in effective communication and appropriate documentation	Hands-on training, especially for new staff and staff with minimal experience. Video recordings of training for staff to review on their own time.

Staff support and incentives	Informal support to staff members Formal support groups for staff members Opportunity to take on a leadership role in psychiatric aspects of long-term care	During visits, a psychiatric consultant can provide direct and situation-specific verbal support to caregivers. A break room for staff members where they can “chill” (massage chairs, relaxing music, yoga videos, and mats).

Psychosocial Environmental Interventions Directed Toward Residents

Type of Psychosocial Environmental Intervention	Examples	Comments/Resources
Environmental	Design of physical environment that accommodates cognitive impairment and promotes emotional well-being Robust activity programming Structured routines Therapeutic gardens	www.healthdesign.org Consultation, staff education, and periodic supervision of the programs by recreational therapist Activity programs run by activity therapist Cognitive stimulation therapy (www.cstdementia.com) www.timeslips.org www.thegreenhouseproject.org
Music-based	Individualized	Consultation, staff education,

strategies	music Group music	and periodic supervision of the programs by music therapists Availability of piano for the residents to play, music CDs, iPod, mp3 players, radio
Physical activity and exercise	Walking programs Chair yoga Tai Chi Dance exercise programs	Guidance, staff education, and periodic supervision of the programs by a physical therapist Staff encouraged to make physical activity a normal part of the resident’s routine
Aromatherapy combined with massage therapy	Hand or foot massage with a fragrant lotion	Consultation, staff education, and periodic supervision of aromatherapy programs by certified aromatherapist Availability of common therapeutic lotions (e.g., lavender and citrus lotions) for staff to use
Animal-assisted therapy	Dogs and cats visiting	Eden Alternative programs (www.edenalt.org)
Emotional support	Support groups	Stroke support group Early-stage dementia support group Chronic pain support groups Parkinson disease support groups Veterans support groups
Counseling	Problem-solving therapy	Facility administration encouraging licensed

	Reminiscence therapy Interpersonal therapy Cognitive-behavioral therapy	psychotherapists/counselors to provide psychological therapies to cognitively capable residents Internet-based self-psychotherapy for cognitively capable residents
Spiritual	Maintaining religious rituals	“Postcards to God” program

Table 55.6a–11.
Eight Key Training Programs for Long-Term Care Staff

Training Program	Resource
Person-centered language training	https://practicetransformation.umn.edu/clinical-tools/person-centered-language/
Bathing without a Battle training	https://bathingwithoutabattle.unc.edu
Mouth care without a Battle training	https://www.mouthcarewithoutabattle.org
Namaste care training	https://namastecare.com/namaste-care-individual-program/
The DICE approach—systematic approaches to address behavioral expressions (aka behavioral and psychological symptoms of dementia [BPSD]) Online training:	https://diceapproach.com
TimeSlips Creative Engagement Training	https://timeslips.org
Cognitive stimulation therapy	https://www.ucl.ac.uk/international-cognitive-stimulation-therapy/international-cognitive-stimulation-therapy-cst-centre

Staff Mindfulness and Resilience Training (SMART sessions)	A psychiatric consultant can provide such training or guide the social worker in providing this training

Table 55.6a–12.

Approach to Appropriate Use of Antipsychotic Medications to Manage Severe Behavioral and Psychological Symptoms of Major Neurocognitive Disorder

Step 1: Presence of at least one of the following:

- Persistent severe agitation and or physically aggressive behavior

or

- Psychotic symptom causing severe emotional distress

Step 2: Assess safety

- The resident poses an imminent danger to themself and/or others. (Address safety first with the following options individually or in combination: one-to-one staff monitoring; use of oral or intramuscular antipsychotic medication; transfer to Emergency Department. When safety is ensured, proceed to Step 3.)
- The resident does not pose an imminent danger to themself and/or others. (Proceed to Step 3.)

Step 3: The treatment team completes a thorough evaluation to look for treatable or reversible causes of the target problems

- Primary care clinician or psychiatric consultant completes history and examination (including pertinent neurologic and detailed mental status examination)
- Complete team discussion to identify treatable or reversible causes
- Order laboratory and other tests as necessary, and results reviewed or testing not required

Step 4: Treat agitation and/or emotional distress with an individualized treatment plan and without psychopharmacologic intervention

- Correct identified causes of target problems
- Team discussion identifies and institutes individualized psychosocial environmental interventions

Step 5: Assess response to treatment

- Adequate improvement and/or the resolution of target problems
- Lack of adequate response to treatment (Proceed to step 6.)

Step 6: Attempt a trial of pharmacologic interventions other than antipsychotics

- Attempt a trial of acetaminophen if there are no contraindications

- Attempt a trial of citalopram (up to 20 mg/day) or escitalopram if there are no contraindications
- Attempt a trial of low-dose trazodone if there are no contraindications
- Attempt trial of a combination of the above medications if there are no contraindications

Step 7: Assess response to treatment

- Adequate improvement and/or resolution of target problem(s)
- Lack of adequate response to treatment (Proceed to step 8.)

Step 8: Make a decision to prescribe antipsychotic medications

- Obtain consent from surrogate decision maker for the use of antipsychotics after adequately explaining the risks and potential benefits of their use

Step 9: Attempt trial of antipsychotic medications

- Attempt trial with one of three atypical antipsychotics: brexpiprazole, risperidone, olanzapine, quetiapine, aripiprazole[a]

Step 10: Assess response to treatment

- Adequate improvement and/or resolution of target problems without significant adverse effects
- Adequate improvement and/or resolution of target problems but associated with significant adverse effects (Proceed to step 11.)
- Lack of adequate response to treatment (Proceed to step 11.)

Step 11: Attempt trial of another of the atypical antipsychotic medications mentioned above

- Adequate improvement and/or resolution of target problems (Proceed to step 13.)
- Lack of adequate response to treatment (Proceed to step 12.)

Step 12: Team discussion (including with surrogate decision maker) regarding further care

- Decide to transfer the resident to a local Emergency Department for acute inpatient psychiatric treatment or to transfer the resident directly to an acute inpatient psychiatric unit in a hospital (preferably a geropsychiatric unit)

- If in keeping with the residents' values and wishes, decide to switch to palliative care (with more liberal use of antipsychotics and, if necessary, short-acting benzodiazepines such as lorazepam to relieve the burden of intractable suffering, even at the cost of excessive sedation) as the resident is in severe to terminal stages of dementia and burdens of transfer to Emergency Department and hospitalization are high and potential benefits low

Step 13: Attempt to reduce and discontinue antipsychotics after 3–6 months of stabilization

- Attempt to reduce and discontinue antipsychotic medication

Step 14: Assess response to dose reduction and discontinuation

- Lack of relapse of target symptoms
- Relapse of target symptoms (Proceed to step 15.)

Step 15: Reinstitute antipsychotics and attempt Step 13 after 3–6 months of stabilization

---

Note: The psychiatric consultant may need to skip steps 5 and 6 if the resident who has a major neurocognitive disorder has behavioral and psychological symptoms that are posing an immediate danger to self and or others. In behavioral emergencies (e.g., violent behavior), immediate use of one or two doses of antipsychotic medication may be necessary to stabilize the emergency situation before stepped-care approach is initiated. If, during step 3, the team concludes that the resident qualifies for end-of-life care, proceed to palliative care directly. Step 12 can be instituted at any point if there is a radical change in the resident's clinical status. Collaboration with a pharmacist is encouraged at every step and in creating a facility-wide initiative to reduce inappropriate use of antipsychotics.

[a] In residents with Parkinson disease dementia or Lewy Body Dementia, Pimavanserin (first line) should be considered for the management of severe psychotic symptoms with quetiapine (second line) as a second-line option. Clozapine may also be considered for treatment-refractory Parkinson disease psychoses.

Case example 2: Mr. M is a 76-year-old veteran living in a rural nursing home in Idaho. His wife is very devoted to him and his primary support. Mr. M has advanced dementia, probable Alzheimer type. Due to the COVID-19 pandemic, the nursing home had to go on lockdown for several weeks. Mr. M became increasingly sad, irritable, and withdrawn. He developed a reduced appetite and lost 15 pounds over 5 weeks. He stopped coming out of his room. Staff instituted a comprehensive individualized pleasant activity schedule that included the following: more frequent phone calls and daily video chats with his wife (this helped his wife cope with stress also), scheduled time to watch his favorite movies on TV (especially Westerns), his favorite food and drinks every day, window visits with his wife three times a week, daily one on one visits with activity therapist (with physical distancing—staying 6 feet away) for 10 minutes where they would engage in a variety of activities depending on his preference (e.g., coloring, listening to music, watching videos of his pet dog that his wife had provided to the nursing home), and bright light therapy 20 minutes daily in the morning. Mr. M has significant receptive and expressive aphasia, due to which cognitive strategies (e.g., reminiscence) could not be done. Once the lockdown status was lifted, his wife was allowed to visit him in person as part of compassionate care visits. Gradually, Mr. M's mood improved, his appetite and weight improved, and he started coming out of his room and smiling more. Initiating antidepressant mirtazapine was considered, but the team, in collaboration with his wife, decided to try nonpharmacologic interventions first.

Clinical pearl: Individualized pleasant activity schedule is an effective intervention to treat depression in individuals with dementia.

Case example 3: Mr. C is an 80-year-old male, married for 55 years, a retired schoolteacher, and father of three children. He has had MNCD, probable Alzheimer type, for the last 8 years. Mr. C had been experiencing severe agitation and aggressive behaviors over the last several months. His wife reported that Mr. C would be “Dr. Jekyll and Mr. Hyde,” at times pleasant and nice but then suddenly would “have a look of hatred” toward her and accuse her of infidelity. Mr. C had been physically aggressive toward his wife, which prompted admission to an assisted living (AL) home. At the AL, Mr. C attempted to choke a female resident, twisted the arm of a female staff member, and made several threats that he would “destroy” the place. Mr. C had also voiced paranoid thoughts that “they” (meaning the staff and residents) were trying to steal his money and belongings. Mr. C’s PCP had done a thorough workup and found no reversible cause, so he had prescribed escitalopram (10 mg daily), donepezil, and as-needed alprazolam. The staff had attempted various individualized psychosocial environmental interventions (e.g., taking him for walks, playing his favorite music in his room), but the aggressive behaviors persisted. At this point, psychiatric consultation was requested to facilitate transfer to a local acute inpatient geropsychiatric unit. After completing a thorough assessment and review of records, the psychiatric consultant encouraged the facility to give a trial of antipsychotics before transferring Mr. C to an acute inpatient psychiatric unit. The facility agreed. The psychiatrist recommended initiation of olanzapine 5 mg at bedtime, discontinued alprazolam, started scheduled acetaminophen as there were some reports from the staff that Mr. C occasionally complained of lower back pain, and added short-term (for 1 week) p.r.n. orally dissolvable 5 mg olanzapine up to twice a day. Over the next 2 weeks, Mr. C’s aggressive episodes improved modestly, and the staff was able to engage him in more individualized psychosocial environmental interventions. After 4 weeks, his wife and the staff felt that Mr. C was much better, although he still had episodes of anger.

Clinical pearl: Judicious use of atypical antipsychotics may help reduce aggressive behaviors by residents who have MNCD and prevent a transfer to the ED.

Depressive Disorders

The prevalence of depressive disorders is high in LTC residents. Hence, the authors recommend assessing all residents for depression within 1 month of admission to an LTC facility and every 6 months thereafter. Residents who have a history of depression, psychiatric hospitalization, and/or antidepressant treatment have shown the strongest association with new onset of depression after admission to an LTCF and thus would benefit from closer monitoring. The period of adjustment to living in LTC can range from a few weeks to 6 months as residents cope with multiple losses, including independence, home, privacy, possessions, and control over their personal schedule. Additional challenges to living in LTC include interaction with peers who have severe MNCD. High staff turnover and a lack of robust activity programming may also contribute to depression.

Standardized scales recommended for assessing depression in LTC residents include the Geriatric Depression Scale, used for residents who have mild cognitive impairment or mild dementia, and the Cornell Scale for Depression in Dementia, used for residents who have moderate to severe dementia. The Patient Health Questionnaire—9 or the Saint Louis University “AM SAD” (appetite, mood, sleep, activity, thoughts of death) may be used in place of the Geriatric Depression Scale.

Workup should include identifying medications that may cause depression (e.g., interferon, propranolol), medical conditions (e.g., pain, hypothyroidism, hyperthyroidism), and neurologic conditions (e.g., stroke) that may cause or contribute to depression. Androgen deficiency syndrome (testosterone deficiency) may cause depression in older men and should be considered in the differential diagnosis. Apathy and hypoactive delirium are often misdiagnosed as depression.

Treatment of depression begins with psychoeducation, rational deprescribing, and optimizing the treatment of medical and neurologic conditions.

Psychosocial and environmental strategies are appropriate and necessary and may be sufficient for the treatment of mild to moderate depressive disorder. Such interventions include psychotherapy (counseling), physical exercise, behavioral activation therapy with an individualized pleasant activity schedule, music therapy, bright light therapy, increasing social support, and complementary and alternative treatments such as yoga, Tai Chi, meditation, massage therapy, journaling, gratitude-based interventions, and aromatherapy. Psychotherapy with the LTC population primarily involves supportive psychotherapy (including reminiscence therapy and life review) with problem-solving strategies (especially for residents who have executive dysfunction) and/or interpersonal psychotherapy components (especially for residents coping with grief or family conflict). With more-capable residents, cognitive behavior therapy may also be appropriate. Meaning-centered psychotherapy is recommended for LTC residents experiencing demoralization. Malnutrition, dehydration, constipation, and pain are common comorbid conditions among residents who have depression and need to be optimally treated for successful outcomes.

Although rigorous studies have not consistently found antidepressants to be effective for the treatment of depressive disorders among LTC residents, most experts and expert consensus guidelines support the use of antidepressants to treat moderate to severe depressive symptoms. The starting doses of antidepressants need to be low, but final effective doses may need to be comparable to those used by younger adults. One of the SSRIs, SNRIs, or mirtazapine is the preferred first-line treatment for depression if the psychiatric consultant opts for pharmacotherapy. Bupropion and nortriptyline are usually the second line of treatment. SSRIs are generally used as first line and SNRIs as second line for the treatment of depression in individuals with PD. Nortriptyline may be preferred over other antidepressants to treat depression for some residents who have PD. The psychiatric consultant should also consider prescribing pramipexole to treat depression for residents who have PD; it may even be preferred over nortriptyline and other antidepressants, as it also improves motor symptoms of PD. The psychiatric consultant may consider prescribing short-term use of low-dose methylphenidate to treat depression with severe apathy to speed up the response to an antidepressant, especially in the context of rehabilitation if the resident is not participating in physical therapy. The psychiatric consultant should avoid prescribing monoamine oxidase inhibitors as well as antidepressants with high anticholinergic activity, such as amitriptyline, imipramine, and doxepin, because of the high risk–benefit ratio. For residents who have an inadequate response to an antidepressant, the psychiatric consultant should consider adding transcranial magnetic stimulation for milder symptoms and aripiprazole as an adjuvant to treat moderate to severe major depressive disorder. Quetiapine and brexpiprazole may also be considered for treatment-resistant depression, although aripiprazole has been studied more rigorously in older adults with major depression compared to quetiapine and brexpiprazole. Electroconvulsive therapy (ECT) is the treatment of choice for severe major depression, especially in medically complex patients, older adults, and for treatment-resistant symptoms. ECT is faster acting than any other intervention for severe depression and can be lifesaving in individuals with severe malnutrition due to severe depression and individuals at high risk of suicide. Intranasal esketamine spray and intravenous ketamine may be considered in select individuals (e.g., individuals with severe depression receiving end-of-life care). Lithium augmentation is effective for treatment-resistant major depression, but its use is limited in the LTC population because of high medical comorbidity (e.g., significant kidney disease and cardiac arrhythmias). T3 thyroid supplementation is also an option for the treatment of major depression not responding adequately to antidepressant therapy. Optimizing hypothyroidism treatment (e.g., getting to a TSH level between 1 and 2) may also improve depression outcomes. A combination of antidepressants and antipsychotics (e.g., sertraline plus olanzapine) may be considered for psychotic depression. Psychotic symptoms in the context of major depression are more common in older adults compared to younger adults. All residents with major depression need to be closely screened for psychotic symptoms as morbidity and mortality are high, and a lack of response to antidepressants is very likely. ECT is the most effective treatment for psychotic depression in older adults.

Case example 4: Mr. L is an 88-year-old widowed male, a retired construction worker living in a nursing home. He has a long history of alcohol addiction and alcoholic liver disease. Psychiatric consultation was made, as the staff felt Mr. L was depressed. The staff reported that for the last several weeks, Mr. L had been refusing to get out of bed, was not eating well, lost 15 pounds, did not enjoy visits from his grandchildren, and had voiced multiple somatic complaints, including dizziness. During the evaluation, the psychiatric consultant found out that Mr. L had had multiple recent losses: two of his children had died of heart disease in the last year, and his pet dog had died 6 months ago (just before he moved into the nursing home), and 3 months ago his house was sold to pay for the nursing home. Mr. L became tearful during the interview. Workup for reversible conditions detected mild vitamin B12 deficiency and mild dehydration. There was no evidence of MNCD, and Mr. L was open to recommendations from the psychiatric consultant, including antidepressants. The psychiatric consultant recommended vitamin B12 supplementation, improved intake of daily fluids, and weekly individual psychotherapy with a psychologist who visits the facility; the psychiatrist did not recommend antidepressants. Over the next 6 weeks, Mr. L showed significant improvement. He started to come out of his room, participated in activities, improved his food intake, gained 2 pounds, and would look forward to visits from his grandchildren.

Clinical pearl: Psychotherapy should be routinely offered to treat depression for cognitively capable residents, and LTC facilities should arrange with local psychotherapists to visit the facility and provide psychotherapeutic services.

Psychotic Disorders

Psychotic symptoms in the context of MNCD are the most common psychotic disorders in the LTC population, followed by psychotic symptoms due to medication and due to general medical and neurologic conditions (e.g., PD, stroke, traumatic brain injury, COVID-19). Dopaminergic agents used to treat PD, anticholinergics, and corticosteroids are the three most common categories of medication that cause and or worsen psychotic symptoms. Psychotic symptoms in the context of affective disorder (major depression as well as bipolar disorders), schizophrenia, schizoaffective disorder, and delusional disorder are becoming increasingly prevalent due to the aging of adults who have a chronic mental illness. Misdiagnosis of schizophrenia, bipolar disorder, and schizoaffective disorder is prevalent in LTC populations. Psychotic symptoms may also be the initial or most disturbing manifestation of delirium. Psychotic symptoms are among the most serious complications of MNCD and are associated with a high degree of emotional distress and accelerated cognitive decline. The psychiatric consultant should consider the new onset of psychotic symptoms among LTC residents as equivalent to delirium, with a thorough workup, including, as appropriate, neuroimaging.

Psychotic symptoms associated with MNCD are typically mild to moderate in severity and are best managed with psychosocial/environmental interventions. Antipsychotics have not been shown to reduce psychotic symptoms related to neurocognitive disorder, and the authors do not recommend their use unless psychotic symptoms are accompanied by severe aggression and or agitation. Management of psychotic symptoms in the context of PD is challenging, as the majority of residents who have PD have PD-related MNCD. Furthermore, only pimavanserin and clozapine have been found to be effective for the treatment of psychotic symptoms in the context of PD. Pimavanserin is approved by the U.S. FDA and is generally preferred over clozapine, although the cost is a significant concern with the use of pimavanserin. The use of clozapine carries even higher morbidity and mortality risk for LTC residents who have PD than for community-dwelling individuals who have PD due to frailty and the presence of significant cognitive impairment. The first strategy is to reduce the dosage of antiparkinsonian agents (such as anticholinergics, amantadine, catechol-O-methyl transferase (COMT) inhibitors, and dopamine agonists with Levodopa reduction as a last resort) and use psychosocial environmental interventions to manage psychotic symptoms. If psychotic symptoms are causing severe distress and agitation, the psychiatric consultant may consider prescribing pimavanserin. For residents who have neurocognitive disorder due to Lewy body disease and are experiencing psychotic symptoms, a trial of rivastigmine or donepezil may help both cognitive and psychotic symptoms (especially visual hallucinations) to a modest extent.

Case example 5: Ms. T is a 71-year-old divorced female, a homemaker, and mother of one daughter and one son, who has a long history of schizophrenia. She was admitted to a nursing home after a stroke. Psychiatric consultation was requested to adjust Ms. T's antipsychotic medication, as she was refusing to participate in physical therapy and making paranoid statements. After completing a thorough evaluation, including a review of records from previous psychiatric hospitalization, the psychiatric consultant confirmed the diagnosis of schizophrenia. Ms. T also had mild neurocognitive disorder due to cerebrovascular disease. The psychiatrist noticed that many staff members felt that Ms. T should be transferred to another facility as they were not equipped to manage chronic mental illness. Ms. T's primary care clinician was also not comfortable managing chronic mental illness by adjusting antipsychotics. Ms. T was taking quetiapine 200 mg daily at bedtime and risperidone 0.5 mg once daily. The psychiatrist increased risperidone to 0.5 mg twice daily for the first week and then 1 mg twice daily and decreased and discontinued quetiapine over 2 weeks. Ms. T showed significant improvement in psychotic symptoms over the next 3 weeks and began to participate in physical therapy.

Clinical pearl: The majority of LTCFs are not prepared to meet the mental health needs of residents with severe mental illness. Psychiatric consultants can play a key role in improving their acceptance by facility staff and help improve the staff's understanding of these illnesses and knowledge about evidence-based strategies to treat them.

Disorders of the Sleep–Wake Cycle

Insomnia, excessive daytime sleepiness, and reversal of the night–day cycle are common among LTC residents. Medications are the most common cause of disorders of the sleep–wake cycle (e.g., SSRI worsening restless leg syndrome [RLS]). RLS and REM sleep behavior disorder (RBD) are prevalent in the LTC population, are often underdiagnosed, and are amenable to treatment. Treatment for insomnia involves discontinuing medications causing or contributing to insomnia (when feasible), optimizing treatment of physical health conditions (e.g., hypothyroidism), and psychosocial environmental interventions (e.g., reducing daytime napping, increasing physical activity, and exposure to sunlight or bright light, following a regular sleep time, soothing bedtime rituals, reducing exposure to noise and light at night). Cognitive-behavioral therapy for insomnia (CBT-Insomnia) and Brief Behavior Therapy for Insomnia (BBTI) are evidence-based interventions for chronic insomnia and are recommended as first-line treatment. Suvorexant is approved by the FDA for the treatment of insomnia related to Alzheimer dementia. Ramelteon and suvorexant may also be considered for the treatment of chronic insomnia. They are safer than other sedative-hypnotics, but the cost is a barrier to their use. The psychiatric consultant may consider prescribing low-dose trazodone (25 to 50 mg) to treat persistent insomnia not responding to psychosocial environmental interventions. The use of hypnotics such as zolpidem, zaleplon, and eszopiclone should be restricted to low doses for short periods of time (days to 2 weeks) (e.g., for a new resident adjusting to living in an LTCF and experiencing significant insomnia) due to a high risk–benefit ratio and regulatory concerns. The psychiatric consultant may consider prescribing low-dose clonazepam and melatonin to treat RBD and may consider prescribing dopamine agonists and gabapentin enacarbil to treat RLS. Dopamine agonists are often used to treat RLS but may cause psychotic symptoms or agitation. Switching to gabapentin, correcting an iron deficiency, leg massages, and evening walking programs may be safer alternatives to dopamine agonists for RLS. Free high-quality apps such as CBT-i Coach from the Veterans Administration are recommended to educate and train the individual in relaxation exercises

Posttraumatic Stress Disorder

Posttraumatic stress disorder (PTSD), nightmare disorder, and subsyndromal PTSD are increasingly seen in the LTC population, not only among veterans but also among civilians who have a past history of abuse or motor vehicular accident, or recent stay in an intensive care unit. LTC staff need education to understand psychological and behavioral manifestations of past trauma and training in care practices to accommodate trauma-related challenges residents typically face. For example, male staff members may not be involved in caring for a female resident who has a history of sexual or physical abuse by a male. Physical restraints are not recommended in general but may have additional negative psychological effects on residents who have a history of abuse. The treatment of PTSD typically involves trauma-centered psychotherapy and, if necessary, antidepressants (especially SSRIs) for anxiety and depression and trazodone for insomnia. Free high-quality apps such as PTSD-coach from the Veterans Administration are recommended to educate and train individuals with PTSD in relaxation exercises. Short-term or as-needed use of short-acting benzodiazepines may be necessary for residents who have PTSD and are experiencing acute anxiety attacks. Low-dose prazosin may be appropriate for the treatment of nightmares in the context of PTSD, although LTC residents are at higher risk than the general population of adverse effects of prazosin, such as hypotensive effects, orthostasis, and falls.

Anxiety Disorders

Generalized anxiety disorder (GAD), panic disorder, and phobias, especially bathing phobia and fear of falling, are prevalent in the LTC population. A bathing phobia is especially common among residents who have MNCD and is best managed by staff training in creative and alternative ways to maintain hygiene using strategies such as towel bathing instead of using a shower. The authors recommend the DVD “Bathing without a Battle,” created by the University of North Carolina, for training all staff members in person-centered strategies to bathe residents who have advanced MNCD. Treatment of GAD and panic disorder typically involves cognitive-behavioral therapy for anxiety (CBT-anxiety), relaxation exercises, and, if necessary, antidepressants (especially SSRIs). Free high-quality apps such as Cleveland Clinic Wellness Mindful Moments and UCLA Mindful are recommended to educate and train the individual in relaxation exercises.

PSYCHIATRIC ASPECTS OF PALLIATIVE CARE

More than 25% of older adults currently die in LTCFs, and the number is expected to rise to more than 40% by 2030. The majority of residents have at least one life-threatening illness, and at least 50% of these have a life expectancy of 2 years or less. Thus, it is imperative that all these residents admitted for long-term stay be offered palliative care as soon after admission as possible. Some residents admitted for short-term stay for rehabilitation may also be appropriate for education about palliative care. Psychiatric consultants can help the staff appreciate that most residents and their family members find the goal of increasing comfort much more satisfying and reasonable than aggressive life-prolonging care. The psychiatric consultant can play a key role in clarifying a resident’s advance care directives, especially in the context of advanced MNCD, where it may be difficult to predict life expectancy, but the burdens of traditional medical care may still be high.

Delirium and depression are two psychiatric syndromes residents frequently experience at the end of life. Psychiatric consultants may be the first health care professionals to identify the resident as in the process of dying and help initiate palliative and hospice care. During end-of-life care, it is appropriate and often necessary to prescribe benzodiazepines to manage anxiety and insomnia, morphine to manage pain and dyspnea, and atypical antipsychotics such as risperidone and olanzapine to manage psychotic symptoms associated with agitation or aggressive behavior. The use of methylphenidate to treat depression during end-of-life care has been recommended for its rapid effect, but among LTC residents, who often have advanced MNCD, methylphenidate may cause delirium or agitation, and thus the psychiatric consultant should closely monitor its use. Palliative sedation may be necessary to relieve the intractable suffering some residents experience during the end stages of life.

Another common reason for referral to a psychiatrist is to evaluate decision-making capacity. Some common clinical situations for such a referral are a resident who has end-stage renal disease and wants to discontinue dialysis; a resident who has depression and is requesting a Do Not Resuscitate status.

55.6b Forensic Aspects

David Naimark, M.D., Keith A. Davidson, J.D., Ariana Nesbit, M.D., M.B.E, and Ansar M. Haroun, M.D. (Retired)

The American Board of Psychiatry and Neurology has recognized both geriatric psychiatry and forensic psychiatry as subspecialties, each meriting its own fellowship training program and subspecialty board examination. The field of “forensic geropsychiatry” is where these two subspecialties overlap, and this subspecialty is growing in its knowledge base and literature. Unlike clinical geropsychiatry, which evolves slowly based on the natural progression of knowledge in the basic psychiatric sciences, forensic geropsychiatry may grow rapidly with abrupt changes based on new laws. Whereas geriatric psychiatry is generally defined by a demographic characteristic (that of age), forensic psychiatry is defined by its ethical duty, to tell the truth, regardless of the effect the psychiatrist’s truth-telling may have on the individual they’re evaluating. This contrasts with the duty of clinical psychiatry, where the clinician’s primary ethical obligation is to the patient’s welfare.

CRIMINAL ASPECTS OF FORENSIC GEROPSYCHIATRY

Epidemiologically, there is a relationship between criminal behavior and age, with an overrepresentation of youthful offenders and an underrepresentation of older adult offenders. Although criminal behavior remains a primary problem for the young, criminality is increasing more rapidly in older adults. This trend may partially be accounted for by the population increase in the total number of older adults; however, there may be an independent increase in criminal behaviors in older adults for other reasons. Possible explanations include the improved efficiency of law enforcement to detect crimes or new patterns of crimes (such as Internet-based crimes) that may be easier for physically disabled elders to commit.

It can be useful to look at the relationship of age to subtypes of criminal behavior. One typology of criminal behavior contrasts crimes that are affective (based on emotion, impulsive) with those that are predatory (coldly calculated, premeditated). While youthful offenders are often hotheaded and at high risk for the former, the older adults are more mature, are less hotheaded, and may be at greater risk for the latter.

The expertise of a geriatric psychiatrist may be needed at several stages of a criminal proceeding. For example, a forensic geropsychiatrist may be asked to opine as to whether the defendant understood their legal rights when they were arrested. Officers are required to inform arrestees of their right to avoid self-incrimination (i.e., to remain silent) as well as their right to counsel. Older individuals or any other persons who may be confused or are cognitively impaired are at risk of not understanding these rights and their associated warnings. If the arrestee does not understand these rights, any statements made in response to police questioning may not be admissible in a court proceeding. In other words, the defendant’s understanding (or lack of understanding) can change the outcome of a legal case by allowing (or disallowing) the statements or confessions. It may be difficult for a psychiatrist to determine whether the defendant understood their rights because many elders are in a gray zone of partial understanding. As a result, what may be relevant was whether the elder spoke to the police voluntarily or through coercion. Although it may be rare for the police to coerce using physical pain, officers may be tempted to coerce using psychological pressures to which the older adults may be especially susceptible (see the following discussion of undue influence). A practical problem that may arise from such possible coercion is that the elder may “confess.” If the confession is voluntary, it is, of course, admissible, but if coerced, it may be challenged. Analysis of the voluntariness of such a confession requires knowledge not only of the behavior of those who elicited the confession (usually the police) but also of the unique psychological and physical strengths and frailties of the confessor.

Competency to Stand Trial

When a criminal trial starts, the court must be satisfied that the defendant is not only physically present but also mentally present and, therefore, able to participate in the trial process (i.e., mentally competent to stand trial). The constitutional competence to stand trial standard requires the defendant to be able to understand the criminal proceedings and to assist their attorney in their own defense in a rational manner. Based on these requirements, a psychiatrist evaluating a defendant’s competence to stand trial will give an opinion on the cognitive status of the elder (whether there is any deficit in *understanding* the nature of the criminal proceedings), the social capacities of the elder (ability to *assist* an attorney), and the rationality of the elder (able to understand and assist in a *rational* manner). Furthermore, in most states, if the psychiatrist detects a deficit in one of these abilities, the evaluator must opine whether the deficit is attributable to a mental disease—thereby making the defendant incompetent to stand trial—or from some other cause. For example, an elder who cannot assist their attorney because of a hearing loss is “audiologically” incompetent but not mentally incompetent. Similarly, psychiatrists must carefully consider the etiology of an older adult defendant’s forgetfulness. If the defendant’s memory deficits are attributable to a mental disorder such as a neurocognitive disorder, then the defendant may postpone or even avoid trial. In contrast, if the forgetfulness is attributable to expected age-related cognitive decline, then it will not qualify for a finding of mental incompetence.

JO, a 72-year-old man with dementia, had a superimposed psychotic disorder at the time of the trial. He had numerous delusions and hallucinations. He seemed to have a basic understanding of the trial process, with the exception of two unusual beliefs: While he could tell the evaluator that the judge oversees the trial and tells the jury the law and the jury is the body that decides, after hearing the evidence, whether he is guilty or innocent, he also had the belief that the judge was an “interloper” and the jury members were “four-footed animals.”

Is this defendant incompetent to stand trial? JO’s competency to stand trial is likely to be controversial. Is his understanding of the function of judge and jury adequate? Does it matter if his conception of the judge and jury is irrational if he knows their function? On the other hand, perhaps he thinks their status as interlopers and animals will make them perform their jobs in a severely substandard way—a way that will deprive him of due process.

Competence to Stand Trial Restoration

If the court finds that a defendant is incompetent to stand trial, the defendant is typically committed to an inpatient treatment setting for competency restoration. Competency restoration generally involves not only the treatment of the individual’s mental health disorder but also education about the legal system and the defendant’s case.

Prior to this treatment beginning, the forensic psychiatrist may be asked to opine as to whether the court may or may not order involuntary medications in order to restore the defendant’s competence to stand trial. In order to order involuntary medications for this purpose, the following criteria must be met:

1. An important government interest is at stake.
2. The medication significantly furthers the state’s interest (e.g., the medication should be likely to restore the defendant’s competence to stand trial and not have severe side effects that would interfere with the trial competency).
3. The medication must be the most appropriate and least intrusive method of restoring the defendant’s competency.
4. The medication must be medically appropriate.

In geriatric cases, the forensic evaluator must be especially careful to balance the risks of medication side effects against the likelihood that the medication will restore the defendant’s competence to stand trial. Geriatric patients may have different responses to medications, which must be separately analyzed in each case. In the case of the elder who has many medical conditions complicating the side-effect profile of the intended psychotropic medication, a different conclusion may be reached than in the case of a nonelder, making it more likely that the court may reject the application for involuntary medication. Some individuals may be restored to competence without involuntary medications. However, if pharmacotherapy is required to restore competence to stand trial, but the court rejects the application allowing involuntary medication, the defendant may be determined to be “permanently incompetent.” Similarly, if the defendant’s incompetence is attributable to a mental health disorder not easily treatable with psychotropic medications (e.g., major neurocognitive disorder due to Alzheimer disease), they may also be deemed permanently incompetent.

Currently, such cases of permanent incompetence are rare because most cases of trial incompetence arise from psychotic disorders, which usually respond to antipsychotic medications.

However, as more older adults enter the criminal justice system, and as more older adults are found to be incompetent to stand trial, it is likely that there will be more cases of trial incompetence from cognitive rather than psychotic disorders. Because some cognitive disorders are reversible and some are not, geriatric psychiatrists will increasingly be asked to separate these two subpopulations. Ultimately, there will be a large group of older adult persons who are permanently incompetent to stand trial. The Supreme Court has ruled that the state cannot hold a person incompetent to stand trial for more than the reasonable period of time necessary to determine whether there is a substantial probability that they will attain that capacity in the foreseeable future. In other words, once a defendant is determined to be permanently incompetent, they can no longer be held under the guise of competence restoration. That being said, permanently incompetent defendants may be able to be civilly committed, which would allow many to remain hospitalized based on their mental disorder, their dangerousness, and, in many states, their grave disability.

Mental Health Defenses

Most criminal defendants are immediately or eventually found competent to stand trial and are, therefore, able to work with their attorney to put forth a defense. During the criminal proceedings, competent defendants may assert any one of several mental health defenses. Mental health defenses vary across jurisdictions, with not guilty by reason of insanity (NGRI) being the most common.

An NGRI defense requires a confession of behavioral guilt ("I did it") but an absence of moral guilt based on a cognitive—and in some jurisdictions, volitional—mental deficit. The most common test of insanity in the United States is known as the M'Naghten standard. The M'Naghten standard states that to establish insanity, the defendant must prove that, at the time of the offense,

> the party accused was laboring under such a defect of reason, from disease of the mind, as not to know the nature and quality of the act he was doing; or if he did know it, that he did not know he was doing what was wrong.

Because older adult defendants are at a greater risk for cognitive deficits, the geriatric psychiatrist should clarify the legal standard in the jurisdiction of practice, especially noting what types of cognitive deficits represent a condition qualifying for an NGRI defense. Although amnesia for the alleged offense is common in older adults, such memory deficits will not qualify for an NGRI defense. In contrast, cognitive deficits in the areas of understanding wrongfulness are more likely to be excused. For example, if a defendant with a neurocognitive disorder fails to recognize his wife and believes that she is an intruder trying to kill him, and if he injures her in self-defense, he may be found NGRI because he did not know that what he was doing was wrong.

Restoration of Sanity

If an elder is indeed found to be NGRI, the state is legally required to make efforts to restore sanity. Generally, a defendant is considered to be restored to sanity when they will no longer pose a danger to the safety of others due to their mental health disorder. In the case of youthful offenders, most of the NGRI acquittals are based on treatable psychotic disorders. But in the case of the elder, the acquittal may be based not on a treatable psychotic disorder but rather on a neurocognitive type, which may or may not respond to treatment. If the defendant's cognitive decline is medically reversible, the court should be informed so that they can order the appropriate treatment. However, if the defendant has an irreversible neurocognitive disorder, this will create a problem for the court: Although the defendant may be confined for treatment, they may not be confined in the absence of treatment because no punishment may be imposed on a defendant who is "not guilty." That being said, in many court cases, the right to treatment is extremely minimal; for example, enough to help keep the defendant out of restraints. In other words, the fact that certain people are effectively untreatable does not mean that they cannot be confined if they are dangerous or gravely disabled. Notwithstanding this, a skillful defense attorney may argue that the elder must be treated or released, thus creating a dilemma for the court.

Sentencing

The forensic geropsychiatrist should be aware of the five possible purposes and philosophies of sentencing: retribution, incapacitation, deterrence, rehabilitation, and restoration. If the purpose of the sentence is punitive (to punish), it is uncommon for a court to seek a psychiatric opinion, although a skillful defense attorney may argue that the very punishment that may be appropriate for a youthful offender may be cruel or unusual for an elder, who may have a reduced capacity to tolerate discomfort. If the court instead focuses on restitution, incapacitation, or rehabilitation, the geropsychiatrist can offer an opinion as to the merits of any of these.

More specifically, a forensic geropsychiatrist may be asked to write a presentencing report to help the court assess for the presence of psychiatric factors that would suggest that the defendant is at a higher or lower risk for reoffending. During sentencing, judges may consider age-related factors like the epidemiologic risk of future harm (lower in older adults), the degree of culpability based on gullibility (older adults may be more gullible and hence less blameworthy), the likelihood of physical violence (lower in older adults), and the likelihood of good compliance with medication to achieve remission of mental illness (which may be lower in medically impaired subjects, whose medical status may make tolerating psychotropic medications more difficult).

Judges may also consider “STAR” factors related to the defendant’s decision making. These objective factors should be noted in a presentencing report for a judge. Subjective factors, such as whether the elder did or did not inspire pity in the examining doctor, should not be given weight. If the doctor is aware of positive or negative feelings toward the defendant that may introduce a bias, the doctor should consult with a colleague and either avoid giving an opinion or give the opinion but clarify why these feelings may have interfered with the psychiatrist's ability to provide an objective opinion.

STAR Factors:

- S: Speed of decision making, with the older adults tending to be more reflective and less impulsive.
- T: Time preference, with mature seniors tending to be more future-oriented than more present-oriented and immature youth.
- A: Elders who have practiced autonomy for most of their lives may be less rebellious toward authority and less determined to demonstrate their independence/autonomy than youthful offenders.
- R: Risk estimation is a function of intelligence and may be poor in both immature youth as well as in cognitively impaired elders. That being said, risk-seeking behaviors tend to decrease with age.

CIVIL ASPECTS OF FORENSIC GEROPSYCHIATRY

In contrast to criminal cases, which involve an action that is considered harmful to society as a whole, civil matters involve a private dispute between persons or organizations. Some of the most common civil matters that a forensic geropsychiatrist may be asked to consult on include testamentary capacity (i.e., the capacity to make a will) and financial and contractual capacity. Other types of medicolegal cases that a geropsychiatrist might encounter include those involving advance directives and medical decision making. Although beyond the scope of this chapter, forensic neuropsychiatrists may also be consulted on cases involving elder abuse or hospital or nursing home malpractice.

GENERAL CONCEPTS IN CIVIL FORENSIC GEROPSYCHIATRY

Decision-Making Capacity and Informed Consent

Civil forensic cases generally require the assessment of decision-making capacity and/or undue influence. Decision-making capacity usually involves the ability to understand a body of knowledge and to rationally apply that knowledge to a decision-making process. In contrast, competence is the quality or condition of being legally qualified to perform an act and/or make decisions. Geropsychiatrists assess an individual's capacity as it relates to their competence. In other words, while the doctor analyzes the decisional capacity and forms a penultimate medical opinion, the trier of fact forms a legal judgment about the ultimate issue: competence.

The principle of respect for autonomy directs psychiatrists to respect patients' choices when they are intentional and made with understanding and without controlling influences (i.e., autonomous). However, in patients with mental health disorders, choices may not always be autonomous due to the fact that they are influenced by the internally controlling influence of a mental health disorder. In these cases, the psychiatrist should recognize that the choice is not truly autonomous and therefore override their decision based on the principles of beneficence and nonmaleficence.

Capacity. In clinical and research settings, a psychiatrist may be asked to opine on an individual's capacity to provide informed consent to medical treatment, to be a research subject, and to die. Capacity evaluations are generally done by analyzing four factors:

1. The patient's preference and the stability of that preference over time
2. Whether the patient has a factual understanding of their medical condition and proposed interventions
3. Whether the patient appreciates the implications of their decision
4. The patient's ability to rationally manipulate the information

Decision-making capacity is required for a patient to be able to provide informed consent. Informed consent is a cornerstone of ethical medical practice, and its goal is to protect autonomous choice. The informed consent process can provide a meaningful chance for a physician and elder to participate in a personalized discussion of risks, benefits, and alternatives associated with a decision in question. In this process, the patient becomes a partner with the physician in the management of the situation, thereby engaging in reasoned decision making. Unfortunately, the informed consent discussion may morph into a procedure done to the patient or subject (i.e., “consenting” the individual). This implies that the elder is a passive recipient of the information who then acquiesces to the decision.

In life outside of medicine, issues of decision making present themselves constantly. Unlike in the medical world, however, the rules around the need for the transactor to obtain informed consent from the transactee become markedly murkier (e.g., does a department store employee need to obtain informed consent before he allows an elder to purchase socks?). Although an individual’s sock-buying capacity is not typically evaluated, geroforensic psychiatrists are often asked to opine on an elder’s capacity to make financial decisions and enter into contracts, make a will (i.e., testamentary capacity), and drive.

Over the last half-century, multiple state and federal court decisions have greatly influenced the analysis of the concept of informed consent. What the doctor must disclose is measured by two standards. The older rule, and one contained in some statutes, is that the doctor must disclose what a reasonable doctor would disclose. The newer rule is the “reasonable patient” standard: The doctor must disclose all material information that they could reasonably expect a patient would want to consider in determining whether to undergo the procedure. Informed consent requires not only that the patient is informed but also that they have the capacity to decide and that their decision should be voluntary. The latter was called into question in one landmark case when an involuntarily committed forensic patient was deemed unable to consent to experimental psychosurgery because the inherently coercive institutional environment prevents voluntary consent.

The first element of informed consent refers to "informed" and asks whether the information from the database (regarding the specific decision in question) was transmitted to the decision maker. It does not assess the state of mind of the transactee and, as such, is the responsibility of the transactor. With inadequate or absent information, the consent would be uninformed, not informed.

The second element of informed consent addresses the "sent" (from the same root as *science*, as in knowledge) and requires the elder to have the mental capacity to understand and appreciate the information provided. The best information in the universe is useless to the elder whose cognitive plumbing is clogged to the degree that it simply can't pass through the pipes of mental functioning. It is here that the forensic evaluator will perform the analysis of decision-making capacity through a mental functioning examination. Mental status deficits, in and of themselves, do not lead to mental incapacity to make a decision. It is only when the observed defect prevents the information from penetrating into the awareness of the subject that the defect becomes relevant. Put another way, mental state defects are a "threshold test": some decisions are complicated and require a maximally functional mental state, whereas others are simple and probably require no more than a marginally intact mental state.

The third and perhaps most misunderstood element of informed consent concerns the "con" part of consent. This distinguishes consent from assent and requires the assessment of whether the elder was able to give a voluntary agreement to the transaction. Lack of voluntariness can be as simple as the overt threatening of an elder unless they agree to a decision or as subtle as the insinuation into a susceptible elder's life to the degree that the elder becomes unduly influenced and thereby unable to give voluntary consent. It is important to understand that "influence" is generally construed to be acceptable, as all human beings influence each other repeatedly every day. It is only when the influence progresses to the point that the will of the elder has been substituted by another's will (generally for the purpose of extracting money or other property) that the court may declare that the influence is undue.

Undue Influence. Although there may be considerable disagreement about when undue influence may exist, there are some circumstances where undue influence likely cannot occur. These circumstances include whether the elder (1) knows their own mind; (2) can distinguish between their interests and the interests of another; and (3) can distinguish a neutral, disinterested assertion from an active, persuasive one.

These conditions emphasize cognitive constructs (i.e., knowing and distinguishing) but leave out issues of emotional knowing. If there is no emotional vulnerability leading to emotional dependence, undue influence is unlikely to occur.

The three elements of informed consent clearly overlap (i.e., mental capacity is related to the ability to give voluntary consent), and the distinction is, therefore, somewhat artificial. It is helpful for clarity, though, for the forensic evaluator to separate the elements as much as possible.

Within the informed consent process, much interest is now focused on the process of informing rather than on the content of information. "Nudging" occurs when information is presented in a different manner in order to improve an individual's decision-making process. Previously, it was assumed that competent patients were rational and, therefore, blind to how information was framed. It is now recognized that most individuals are not blind to framing effects but rather influenced by them. For example, when a doctor informs a patient of the risks of medical treatment, the doctor has the choice of framing the information in positive terms ("75% probability of success") or in the alternative ("25% probability of failure"). The two pieces of information are mathematically equivalent, and a rational agent should be indifferent to how the information is presented. However, most patients process these two pieces of information differently and are likely to reach different conclusions depending on the presenting frame. Whether "nudges" are ethical remains controversial and depends on whether the specific nudge supports or undermines the individual's dignity, welfare, and autonomy.

GENERAL PROCEDURE TO ASSESS UNDUE INFLUENCE. The question of undue influence frequently arises in civil geriatric forensic cases. Undue influence can be defined as the pressure applied unfairly by an individual attempting to manipulate or deceive with the intent of causing that person to make a certain decision. Although every jurisdiction has different elements for undue influence, undue influence generally requires an element of coercion that overcomes the free will of the individual being influenced, thereby robbing the individual's autonomy.

EVALUATING FOR UNDUE INFLUENCE. A forensic geropsychiatrist should consider four elements when assessing the presence of undue influence.

1. Vulnerability of the victim
2. The influencer's apparent authority
3. The actions or tactics used by the influencer
4. The equity of the resulting decision or action

Undue influence may impact an elder's ability to make autonomous decisions related to finances, contracting, medical, and will or trust creation.

Vulnerability of the Victim. This element is the most relevant to geropsychiatric involvement because it requires a finding of at least one of the following conditions: incapacity, illness, disability, impaired cognitive function, emotional distress, isolation, or dependency. Typically, it is the judge or jury who will decide whether this element has been met in a legal trial; however, courts rely heavily on medical expert opinions. These opinions are required in most cases for two primary reasons: (1) hearsay; and (2) interpretation of medical information.

First, nearly every diagnostic conclusion or opinion contained in a written medical record is considered hearsay or an out-of-court statement. Therefore, medical records cannot be used as evidence at the time of trial. Instead, a medical expert must review the records and then give an opinion as to the victims' vulnerability or susceptibility to undue influence. Second, oftentimes medical records have legal terms and jargon that are not easily understood by judges or juries. A medical expert can help interpret medical records to enhance (or perhaps decode) their understanding at trial.

It is interesting to note that judges and juries are allowed to accept either party's expert opinion or reject them both. Under the law, the trier of fact (judge or jury) has the final say as to whether a victim was, in fact, vulnerable to undue influence. The law notwithstanding, medical experts provide a valuable service to help the trier of fact reach their final decision.

Influencer's Apparent Authority. An influencer's apparent authority focuses primarily on the relationship between the influencer and the victim. Relationships that create an increased risk of undue influence include fiduciaries, family members, care providers, health care professionals, legal professionals, spiritual advisers, financial advisers, and experts. Unlike the vulnerability element discussed above, this element focuses on the wrongdoer's position of power over the victim.

Actions or Tactics Used by the Influencer. Actions and tactics focus on the bad acts undertaken by the influencer to suppress the free will of the victim. Actions and tactics include controlling necessities of life, medicine, and access to family and friends, using affection, intimidation, or coercion, initiating changes in personal or property rights, using secrecy in making financial changes, or making changes at inappropriate times and places.

Equity of the Decision or Action. Equity is a legal concept that refers to the fairness of the result. If a person has a long history of benefitting family members under their will and then suddenly changes that plan to benefit a caretaker, this could be viewed as an inequitable result under the circumstances. While equity, by itself, is not enough to establish undue influence, an apparent inequitable result can be persuasively used to help support the other elements of undue influence.

PRESUMPTION OF UNDUE INFLUENCE. Most jurisdictions have a general presumption that undue influence exists where: (1) a confidential relationship exists between the influencer and the victim (much like the apparent authority element discussed above); (2) the influencer actively participated in the procurement of the decision or action; and, (3) the influencer unduly benefitted from the decision or action taken. Where a presumption exists, it is then the burden of the influencer to prove the absence of undue influence, which can be difficult to accomplish in most cases.

Competency to Make Medical Decisions or Consent to Be a Research Subject

While the "meat" of the medical/research capacity evaluation is the forensic interview, there are certain standardized assessment instruments that may be useful. More specifically, the MacArthur Competence Assessment Tools have been shown to have good validity and reliability in multiple populations. Included are semistructured interviews for evaluating the four aspects of decision-making capacity, as described in the previous section. Recently, a new instrument for assessing decisional capacity for clinical research was validated: The University of California, San Diego, Brief Assessment of Capacity to Consent (UBACC) is a 10-item scale focusing on understanding and appreciation of information contained in a research protocol. This Assessment was found to have good reliability and validity while taking less than 5 minutes to administer.

Recent research suggests that certain procedures for "enhancing" informed consent for research and treatment may be helpful. Effective interventions include corrected feedback, multiple learning trials, and well-organized simplified consent forms. Even in older adult individuals with psychotic disorders, enhanced consent procedures involving a computerized slideshow have recently been shown to improve understanding of research consent. When older adult persons are incapable of deciding whether to participate in research, the question arises whether their family—or some other proxy—may consent on their behalf. The federal regulations allow a legally authorized representative (LAR) to do so while leaving the question of who may serve as a LAR to the states. A study of the state regulations shows variability in the statutes, with most states not weighing in on whether families may consent. The important questions that remain are whether proxies are/should be permitted to consent to research on behalf of an incompetent subject; if so, who may/should serve as available proxies and in what order; and whether there are/should be limits on when proxies may decide in the research context. Further study of these issues is warranted, as is gathering data on what is actually being done and how well it is working.

Competency to Make Decisions About Death and Dying

Over the last two generations, there has been a change in societal attitudes to death and dying, and this is reflected in the way in which geriatric patients may view this topic. Throughout history, life has been mostly valued and cherished, while death has been feared. The respect given to the healing professions stemmed partly from the ability of the healer to prolong life and postpone death. But recently, scholars from both medicine and medical ethics have looked more critically at what should be valued in life, its quantity or quality. There is now a school of thought that argues that it is the quality of life that is more valuable and that if a good enough quality of life is not possible, death should not be feared and postponed at all costs but rather considered and possibly welcomed.

Older adult patients may raise questions about treatment refusal, suicide, physician-assisted suicide, and euthanasia. If an older adult patient indicates that they want to refuse treatment in an attempt to promote death, the psychiatrist should determine whether the individual has decision-making capacity. If the decision to seek death is causally related to a mental disorder, then the ethical task is simple: treat the mental disorder, and reassess. On the other hand, if the elder's decision to seek death is rational and not related to a mental disorder, the patient may have the capacity to refuse treatment, even if that refusal may hasten death.

In such cases where there is a clash (real or apparent) between law and ethics, the clinical geropsychiatrist should seek consultation from a forensic colleague. The forensic specialist may then advise the clinician that the principle of respect for autonomy requires that the health care provider respect patients' choices when they are intentional and made with understanding, without controlling influences. The Doctrine of Informed Consent also balances the competing demands from law, ethics, and psychiatry. The clinical psychiatrist should ensure that all three elements of informed consent are met. Because such cases have the potential for careful scrutiny by legal agencies, ethics committees, and the media, the psychiatrist should document how the elements of informed consent were met in detail.

Physician Aid in Dying. Suicide has historically been condemned on moral and religious grounds. With the emergence of psychiatry in the mid-19th century, suicide started being conceptualized under a medical framework, and it was thought of not as a choice by an autonomous agent but rather as a symptom of a mental health disorder. However, over the past several decades, the medical model has been challenged, and some argue that suicide can be rational in some cases. This movement is reflected by the fact that, since 1997, 10 states have adopted statutes that allow individuals to request lethal prescriptions that they can choose to ingest if two physicians agree that the patient has decision-making capacity and an irreversible, terminal illness likely to lead to death within 6 months.

In states where physician aid in dying (PAD) is legal, geropsychiatrists may be asked to evaluate a terminal patient's capacity to consent to PAD. One of the key questions that the geropsychiatrist will attempt to answer is whether the patient's request for PAD is driven by a diagnosis of depression or whether it reflects a rational and autonomous choice free from the controlling influence of a mental health disorder. This can be a complicated determination, given that suicidal ideation is itself a symptom of depression. These evaluations are also complicated because no guidelines for the assessment of capacity to consent to PAD have been broadly agreed upon. Forensic psychiatrists should be aware that, without set standards for assessing such decision-making capacity, they may use themselves as the “reasonable person” by which to judge the patient’s request for PAD. In other words, their own personal beliefs about PAD may influence their capacity evaluation.

Competency to Make a Will

A forensic geropsychiatrist is most often called upon to evaluate an individual’s capacity to make a will after the elder is deceased and the will is being contested. However, some lawyers arrange psychiatric evaluations of their clients at the time of the will creation in order to avoid later disputes about testamentary capacity.

The level of capacity to create a will, referred to as “testamentary capacity,” is measured using two different standards. First, there is a three-part test in most states that determines whether the person creating the will understands (1) what they are doing in making a will; (2) the nature and extent of their property (i.e., a general recitation of what a person owns, not specific details); and, (3) the “natural objects of their bounty” (i.e., their relation to living descendants, spouse, and parents, and others whose interests are affected by the will). Most jurisdictions require evidence of a mental defect that has a direct correlation to the individual’s ability to understand one of these three elements. A series of eccentric or odd behaviors will not, in and of itself, establish a lack of capacity under this standard. However, a mental defect, such as impaired cognitive functioning that directly affects at least one of the three parts listed above (e.g., an individual’s ability to understand the natural objects of his bounty), would qualify as a lack of capacity under the three-part test. A person must understand all three parts of the capacity standard to have testamentary capacity.

Second, the person must not suffer from a mental disorder that involves delusions or hallucinations that have an effect on the particular bequest. Under this standard, a delusion or hallucination alone is enough to find a lack of testamentary capacity, but only if the delusion or hallucination has a direct correlation to the dispositions under the will. The “insane delusion” standard is hard to meet: The delusion must be extreme, and the individual must cling to the delusion in the face of uncontroverted contrary facts. For example, a belief that one’s family no longer loves one would not be an insane delusion even if it is untrue and not well grounded in evidence: It *could* be true. By contrast, a belief that one’s family is trying to kill one with ray guns would be an insane delusion. Similarly, a belief that one’s child is the product of adultery and not really one’s child will typically not be considered an insane delusion. However, a belief that the child has been taken over by aliens, and is not really one’s child, would. In addition, the delusion must affect the bequest. If the individual has another independent (sane) reason for the bequest, then the delusion does not vitiate their testamentary capacity.

Mr. Jones was an unmarried 75-year-old male with three children. One year prior to his death, he began exhibiting strange behavior. He would repeatedly visit his neighbors and offer to buy all of the furniture in their homes even though the furniture was never for sale. Mr. Jones would also make crank calls to local pizza parlors. Over the course of 12 months, he refused to let any family members or friends into his home and would send gifts through the mail that typically consisted of a whole fish or raw meat. Mr. Jones was never diagnosed with any form of dementia or mental defect causing cognitive impairment. Upon his death, Mr. Jones' will was discovered. The will was created 6 months before Mr. Jones' death, and he left his entire estate to his church. Did Mr. Jones have the legal capacity to create his will?

Mr. Jones likely had the requisite legal capacity to make his will. The law in this area presumes that decedents have capacity until proven otherwise. Even though Mr. Jones exhibited eccentric and strange behavior prior to his death, there is no evidence that he had a mental defect that directly affected his ability to understand the objects of his bounty, the fact that he was creating a will, and the general nature of his property.

Undue influence is commonly used in attempts to overturn a decedent's will. Undue influence requires (1) vulnerability of the victim, (2) apparent authority of the wrongdoer, (3) actions and tactics of the wrongdoer, and (4) equity of the result. Lessened capacity generally makes a subject more susceptible to undue influence. Although the lessened capacity may not be enough to prove a lack of capacity, it could provide support for a successful undue influence claim, provided the other elements of undue influence are present. In the example above, there are no facts to support the other elements of undue influence, but if a wrongdoer was present and exerting pressure on Mr. Jones (see box above) to leave all his assets to him, then there could be a claim for undue influence.

Roger is an 83-year-old wealthy business executive. Roger is married to 81-year-old Jenny, and they have two daughters, Wendy and Sally. For the past 20 years, Sally has worked in Roger's business, where she oversees all of his finances. Roger was advised to start gifting some of his assets to his children and grandchildren so he would not be subject to estate tax on his death. He instructed Sally to prepare checks of $10,000 each for Wendy, Wendy's two children, Sally, Sally's one child, and Sally's husband. Wendy became enraged when she learned that Sally's husband received a $10,000 check, but her husband did not. A few weeks after the checks were written, Roger died. Wendy then went to Jenny and told her that Sally was stealing money, could not be trusted with the funds, and that Sally was trying to take Jenny's assets. Jenny becomes alarmed and immediately fires Sally from the business. She cut off all communications with Sally. Wendy then moved Jenny into her home to care for her. Wendy was given a power of attorney to manage the finances, and Wendy began overseeing the family business. Jenny then created a new will, leaving all assets to Wendy, and disinheriting Sally. To note, all previous wills gave everything equally to the two daughters. Sally attempted to talk to her mother, but Wendy refused to let them speak and refused Sally entry to her home to see Jenny. During this time, Wendy frequently told Jenny that Sally was trying to be nice to her so that she could steal more money. Jenny died, and Wendy believed she was entitled to everything.

Was Jenny unduly influenced to create her will leaving everything to Wendy? The first question is whether Jenny was susceptible to undue influence. There are signs that Jenny may indeed be susceptible to undue influence due to the death of her husband, her age, and the fact that she so readily believed Wendy's wild claims. A forensic geropsychiatrist evaluating this claim would investigate Jenny's medical records to determine her level of mental functioning, remembering that Jenny need only have a weakened mental state, not a complete lack of capacity because the remaining elements of undue influence focus on the actions of Wendy. Wendy had apparent authority over Jenny both as a trusted daughter and as an agent under Jenny's durable power of attorney. Wendy used suspicious tactics in keeping Jenny secluded and refusing to allow Sally to see Jenny. The resulting will was unlike any past will, where the estate was divided equally.

This example also highlights the "poisoning of the mind" that occurs when an elder is secluded and manipulated by a single child. In this example, undue influence was present, and the will could therefore be set aside.

Competency to Make Financial Decisions or Contract

In contrast to testamentary capacity, which is often questioned retrospectively when the elder is deceased, the question regarding whether an individual has the competency to make a financial decision usually occurs when the patient is alive. For example, a forensic geropsychiatrist may be asked to provide an opinion on an elder's capacity to make financial decisions in the context of a dispute involving an elder's right to give money to a person of their choosing, particularly when there is a concern that the elder is being financially exploited.

Generally, in order to be found legally competent to make financial decisions or contracts, the subject must be able to understand and appreciate, to the extent applicable:

1. The rights, duties, and responsibilities created by or affected by the decision
2. The probable consequences of the decision
3. The significant risks, benefits, and reasonable alternatives involved in the decision

A financial decision or contract can also be overturned based on the legal concept of undue influence. In this context, undue influence focuses more on the actions of the wrongdoer and looks to mental functioning only to determine if the subject is vulnerable or susceptible to undue influence. In other words, a person can be susceptible to undue influence but still have the requisite legal mental capacity to make a financial decision or contract. Courts tend to be wary of overturning an elder’s capacity to make decisions regarding whether to enter into contracts or make financial decisions, whereas they are more liberal with protecting an elder from possible undue influence perpetrated by another.

Diane is an 85-year-old female who has always been independent and refuses to talk about her finances with her only daughter, Tina Smith. Tina lives in San Francisco, while Diane lives in Los Angeles. Diane owns the home she lives in as well as three other homes on the same block, which she rents out to various tenants. One of Diane's neighbors, Ned Riley, is a handyman who has helped her repair her properties and various other odd jobs throughout the past 10 years. Diane's mental functioning has slowly declined, and she has started having trouble walking. Ned and his wife, Brenda, started assisting Diane with grocery shopping, taking her to medical appointments, and obtaining her prescription medicine. After several months, Brenda takes over Diane's checkbook and starts paying her bills. Brenda writes all the checks by hand and then has Diane sign the checks. After 10 months of assisting Diane, Ned and Brenda create a corporation and enter into a contract between Diane and the new corporation to "buy" Diane's three rental properties by paying a $1,000 down payment and agreeing to make payments of $1,000 per month. They set the total purchase price for all three properties at $300,000. Each rental property is worth over $250,000, making this sale arrangement a below-market bargain for Ned and Brenda. After the initial down payment, no other payments are made, and all rental income goes directly to Ned and Brenda. After a year of this arrangement, Diane runs low on funds and cannot pay for her prescriptions, which is the first time Diane mentions her finances to her daughter. Tina hires a lawyer and discovers the "sale" arrangement as well as the neighbors' actions with Diane's checkbook.

A forensic geropsychiatrist evaluating Diane may be asked to consider both her contractual capacity as well as whether she was unduly influenced to make the financial decisions described above. Her contractual capacity would be evaluated using the elements pertaining to her capacity to make a decision. Although the above facts do not provide enough details to fully evaluate capacity, the mere fact that the properties were sold at a substantial discount suggests that Diane may have had difficulty understanding the consequences of that decision.

In addition, the facts of this case are typical of the pattern of behavior found in many undue influence claims: the neighbors started by being helpful and slowly took over more and more jobs for Diane. Such actions build trust and goodwill with Diane. Over time, the neighbors used that trusting relationship to convince Diane to enter into a bargain sale of the properties. The first step in evaluating an undue influence claim is to determine Diane's susceptibility to undue influence. The forensic geropsychiatrist would then consider the actions and tactics of the neighbors and their position of trust with Diane, and the inequity of the result. Capacity and undue influence are separate claims that can be evaluated at the same time; one claim can succeed where the other fails, or they both can be established where the facts are sufficient.

Competency to Drive

Loss of driving privileges is, after nursing home placement, the most feared event for an older adult person. Age alone does not cause impairment behind the wheel; however, impairments associated with neurocognitive disorders can. Geriatric psychiatry training rarely provides specific instructions on how to complete a driving assessment. Therefore, many states require that a physician make a referral to the Department of Motor Vehicles (DMV) if a major neurocognitive disorder is diagnosed but do not require the physician to state whether the patient can or cannot drive.

After a case is referred to the DMV, screening test administrators evaluate whether the elder has the four mental requirements to drive:

1. Proper integration of sensory input
2. Focus of attention
3. Proper association of thought

4. Appropriate judgment

Advanced Directives

Advance directives are instructions regarding the patient’s preferences for medical care if they become incapacitated that are designed to promote an individual’s autonomous decision making. One type of advance directive is a living will, which addresses a patient’s wishes for life-sustaining procedures and end-of-life treatment. The second type of advance directive is a durable power of attorney for health care, where a patient designates another person the authority to make decisions for themselves in the event of incapacity. Although hospitals are required not only to ask patients whether they have medical advance directives at the time of admission but also to provide their patients with information about advance directives, most patients nevertheless still do not have such documents.

More recently, psychiatric advance directives have been promoted as a means by which patients with mental health disorders can describe their preferences for psychiatric treatment in the event that they become incapacitated. Psychiatric advance directives can include information such as medication preferences, helpful de-escalation, coping techniques, and a list of individuals that the patient would like involved in their care. Currently, only 25 states have specific psychiatric advance directive statutes. However, for patients in states without specific psychiatric advance directive laws, general medical advance directives can be used to direct some types of psychiatric treatment.

ADMINISTRATIVE ASPECTS OF FORENSIC GEROPSYCHIATRY

The Older Adult Impaired Physician

Life expectancy is rising in most Western societies, and upper-income, highly educated persons like physicians are likely to live and work even longer than the national average. Impediments to working in old age may include physical infirmities (e.g., a Parkinsonian tremor may cut a surgical career short) or mental infirmities (e.g., mild cognitive impairment). If the affected individual is a physician, this is most likely to come to the attention of a medical board through a complaint made by an unhappy patient, usually after a bad clinical outcome.

The geriatric psychiatrist may be asked to evaluate the older adult physician in order to help the medical board reach a conclusion regarding the physician's license. The evaluating geropsychiatrist should avoid giving a conclusion (i.e., "the doctor should keep or not keep their medical license") because this ultimate opinion is the decision of the medical board. Instead, the forensic geropsychiatrist should answer only the specific question(s) asked. For example, the forensic geropsychiatrist may be asked to diagnose the physician in question. They may also be asked to evaluate the various strengths and weaknesses in the elder's capacity to plan, organize, sequence and abstract (i.e., the executive functions), and identify any related impairments.

Older Adult Applicants for Disability Benefits

Public or private provisions protect working individuals against losing all income in the case of a physical or mental disability. In the public sector, most citizens are covered by the Social Security Administration's (SSA's) policies. In the private sector, there are many insurance companies that offer disability benefits that will provide the individual with greater financial benefits than what would otherwise be offered through the SSA. Unlike in the private sector, SSA provisions are not designed to generate a profit but instead are built to ensure that no disabled person is unable to provide for themselves if they lack the capacity to work. Forensic geropsychiatrists may be asked to evaluate individuals applying for disability in order to determine whether the applicant meets the SSA's or the private insurance company's definition of a disability.

If consulted on an SSA disability case, the geriatric psychiatrist should resist the temptation to give an opinion about the ultimate issue (i.e., the claimant can or cannot work), which is an administrative instead of medical judgment based on social security law. Rather, the doctor should give an opinion regarding the penultimate medical issues. These evaluations can be complicated because there is a normal decline in performance with age in concentration, persistence, and pace. The SSA will then ask the psychiatrist to rate any impairments in severity.

Evaluating for Disability. The geriatric psychiatrist should determine whether the applicant meets the criteria for a qualifying mental disorder, as well as the quality and quantity of impairments in four areas:

1. Activities of daily living
2. Social functioning
3. Concentration, persistence, and pace
4. Decompensations

The SSA guidelines are sensitive to the demands of age. In other words, the same level of impairment may result in a failed claim if the applicant is young but succeeds if the applicant is an older adult. If an impairment is present, the doctor should relate it to a causal factor, which could be a mental disorder (e.g., major neurocognitive disorder) or another complicating factor (e.g., lack of English language skills). Based on the evaluating psychiatrist’s opinion, the SSA will then determine whether the applicant does or does not qualify for disability benefits.

CORRECTIONAL ASPECTS OF FORENSIC GEROPSYCHIATRY

Opportunities for the geriatric psychiatrist to provide clinical services within the correctional system abound and are likely to increase exponentially over the ensuing years as the population ages. It is important to recognize that the correctional psychiatrist *treats* the incarcerated elder and hence plays a different role than the forensic psychiatrist, who *evaluates* the incarcerated elder to truthfully answer a medicolegal question. Over the past 10 years, awareness of the impending problem of the rising number of older adult prisoners has increased. Virtually every major newspaper in the United States has run a story on how the “graying” of the incarcerated population is likely to present a serious ethical or moral challenge as well as an economic crisis for the penal system. There are currently more than 125,000 prisoners over the age of 50 and 35,000 prisoners over the age of 65 in U.S. correctional facilities. Due to sentencing laws and demographic shifts in the population, the U.S. Census Bureau estimates that in 2030, one-third of the jail population will be over 55 years of age.

The geriatric correctional psychiatrist may consider whether an aging prisoner should be released. There are a number of considerations: 97% of older adult inmates are nonviolent offenders, and less than 1% of those on probation or parole who are returned to jail or prison are older than 60. Furthermore, the poor health conditions of prisoners combined with harsh prison life make the prison environment particularly conducive to fostering disease. There is, however, no legal statute that is likely to provide elders with any specific rights beyond the general right to medical care and the right to be free from cruel and unusual punishment. A related question is whether age should be a basis for execution exemption. There are presently over 100 people aged 60 or over on death row. The Supreme Court has ruled that it is unconstitutional to execute certain special populations (e.g., juveniles and those with intellectual disabilities), given that executing these vulnerable populations would violate the Eighth Amendment’s prohibition against cruel and unusual punishment. However, there is no specific prohibition against executing older adults. Therefore, unless the older adult defendant does not understand why they are being executed (i.e., unless they are found incompetent to be executed), they are unlikely to be exempt from the ultimate punishment.

NOSOLOGIC/THEORETICAL ISSUES

In routine clinical practice, most geropsychiatrists use the Diagnostic and Statistical Manual (DSM) or equivalent International Statistical Classification of Diseases and Related Problems (ICD) and follow the “spirit” of the text.

Testifying in Court

In court testimony, the doctor swears to tell the whole truth, and if the diagnoses do not follow the letter of the text, the doctor must truthfully acknowledge that. But the truth may be difficult to determine because forensic geropsychiatrists are often asked to clarify boundaries that may be fuzzy, including the boundaries between the following:

1. Cognitive disorder/age-related cognitive decline
2. Antisocial personality disorder/adult antisocial behavior
3. Depressive disorder/bereavement

In the accompanying box, the first example is a mental disorder, and the second is not. The boundary between the two is often vague and ill-defined, and there may be temptations to place the boundary in a manner that promotes values that promote the well-being of the evaluee; for example, for policy-based (access to care) rather than scientific (nosology) reasons. Although some may consider it admirable for the clinical geropsychiatrist to be compassionate or to advocate for greater access to health care for untreated patients, the forensic geropsychiatrist subscribes to a code of ethics that emphasizes truth-telling rather than the traditional ethical values of promoting health.

Future research in forensic geriatric psychiatry may therefore be of two types: quantitative (i.e., data-based) or qualitative (i.e., conceptual). Quantitative research may focus on the sciences pertaining to nosology, such as clarifying the proper boundaries of the various mental disorders that may be a basis for forensic opinions. Future quantitative research may also help to better delineate the pathways—cognitive, social, moral, logical—of good and bad judgment that often form the basis of findings of mental incompetence in older adults. Future qualitative research may help integrate findings from the biomedical aspects of geropsychiatry with the implications of such findings. For example, whether or not a neurocognitive disorder is curable may alter the legal protections for the rights of the older adult mentally ill and may raise ethical concerns regarding the allocation of limited health care resources to a population of older adults that may have unlimited growth.

55.6c Ethical Issues

Nathan Fairman, M.D., M.P.H.

Elsewhere in this volume, one can find both a broad overview of psychiatric bioethics and a more particular treatment of key ethcial issues at the intersection of palliative care and mental health. Given the excellent coverage of these and other aspects of psychiatric bioethics in this textbook, it's worth asking: *why include a separate chapter on ethical issues in geriatric mental health?* After all, the ethical challenges in old-age psychiatry are, at their core, no different from the ethical challenges one can encounter in the care of nonolder adult mental health patients or, for that matter, in the care of patients without mental illness. However, the myriad changes that accompany aging—developmental, physical, social, cognitive, and others—intersect with mental illness in ways that repeatedly bring ethical concerns into the foreground of patient care. As a result, taking care of older adults with mental illness involves navigating a set of common ethical issues which, while similar in kind to those seen in other populations, differ in their complexity and consequences.

The chapter begins with a reflection on the Principlism paradigm and the way in which it focuses our attention and organizes how we've come to understand ethical obligations in geriatric mental health. Next, the chapter considers two related ethical constructs that are particularly important in geriatric mental health: informed consent and decision-making capacity. The rationale for this focus is that many of the common ethical challenges in geriatric mental health involve questions about respect for autonomy and personhood, particularly in cases marked by cognitive deficits or affective states that can influence decision-making. Careful attention to decisional capacity and informed consent can help ensure ethically responsible care in a population that is sometimes vulnerable to impaired decision-making. A further rationale for this area of focus is that, in many cases, older adults with chronic, life-limiting illnesses eventually face decisions that can influence the timing of death—a circumstance that may seem to "raise the stakes" surrounding questions of informed consent and decisional capacity. Finally, the chapter closes with a patient case that illustrates some of these challenges and presents an ethically responsible approach to caring for a depressed older adult with serious illness and a desire to die.

THE FOCUSING EFFECT OF A FRAMEWORK

Principlism has, since its emergence in the late 1970s, been the predominant ethical paradigm in western medicine. In their *Principles of Biomedical Ethics,* Tom Beauchamp and James Childress identified four core principles of bioethics: respect for autonomy, nonmaleficence, beneficence, and justice. Each principle gives rise to particular duties or responsibilities that health care providers must meet when they care for patients. A true ethical dilemma occurs when the duties that arise from two or more principles are in direct conflict with one another.

Principlism has been criticized from several directions. In regard to geriatric psychiatric ethics, one particular criticism warrants mention: Principlism assigns a high level of moral value to personhood and individualism, and as a result, the framework has a difficult time accommodating the values of nonwestern, communitarian cultures and worldviews. Hence, some of the circumstances that create an apparent ethical dilemma from the view of Principlism may become less salient ethically when viewed through the prism of a different ethical framework. Our social embeddedness as human beings and the very particular, idiosyncratic details of any individual circumstance aren’t given much real estate in the Principlist landscape of ethical value. Nonetheless, Principlism continues to be the predominant bioethical framework in contemporary western medicine, and it does provide a useful way to conceptualize common tensions that occur in geriatric mental health care. The important thing to notice is that the Principlism framework itself focuses our attention, repeatedly, on particular circumstances of geriatric mental health that often produce tension between the obligations of two core principles: respect for autonomy and beneficence.

This brings us to two important reasons that ethical challenges (according to Principlism) frequently occur in the setting of geriatric mental health: first, conditions that are common in old age and in mental illness often undermine an individual’s ability to exercise autonomy. In an ethical sense, such individuals can become vulnerable because various diseases (mental, physical, etc.) erode their capacity to make autonomous, informed choices. Second, there is a unique way in which cognitive decline and mental illness can destabilize the notion of “personhood,” which is central to Principlism. Whose autonomy is to be respected, for example, when severe Major Depression or an advanced Neurocognitive Disorder can so thoroughly and fundamentally alter the present “personhood” of a previously healthy individual? Other medical conditions do not have the power to confuse us about the target of our ethical obligations in the same way that mental illness and severe cognitive changes can.

GENERAL APPLICATIONS OF THE CORE PRINCIPLES TO GERIATRIC MENTAL HEALTH CARE

Several general applications of the principles of bioethics to geriatric mental health care warrant mention. For example, dignity is often a paramount consideration in geriatric mental health. As a result of the stigma associated with neuropsychiatric disorders, as well as the loss of function and status that can be associated with neurodegenerative conditions, patients and loved ones often view health-related decisions through the prism of concerns about dignity. A clinician's efforts to preserve her patient's dignity reflect an ethical commitment to respect her patient's autonomy and personhood. Similarly, the right to confidentiality can also be viewed as an extension of the core principle of respect for autonomy. In the context of work with decisional-impaired adults, confidentiality issues can be particularly complex, as there is often a need to work closely with family members and caregivers, sometimes requiring the disclosure of information at a level that would be uncommon (and perhaps inappropriate) with a patient whose decisional capacity was intact.

Justice considerations, for example, can be relevant to the development and testing of psychotropic medications in older adult populations. Historically, older age patients have been underrepresented in clinical trials of antidepressants and other psychotropic medications. Given potential age-related changes in pharmacokinetics and pharmacodynamics, as well as the increased likelihood of drug interactions from polypharmacy, the need for clinicians to extrapolate from data collected from samples of younger patients raises ethical concerns in terms of justice (in addition to nonmaleficence). The example also illustrates that ethical dilemmas are not always best conceptualized or addressed at the level of individual clinician and patient interactions but may also occur and require change at the level of public policy—in this case, with respect to setting national (or international) research requirements and priorities.

OPERATIONALIZING RESPECT FOR AUTONOMY: DECISION-MAKING CAPACITY AND THE DOCTRINE OF INFORMED CONSENT

As noted above, ethical dilemmas in geriatric mental health often arise from apparent opposition between two core principles: respect for autonomy and beneficence (and its corollary, nonmaleficence). In other words, the conditions of mental illness and advancing age frequently combine to produce circumstances that make it seem impossible to know how to meet those ethical obligations or impossible to satisfy both of them at once. What's more, such conflicts can be particularly difficult to resolve when the weighing of considerations from competing principles is highly subjective, that is, in those instances wherein reasonable people might disagree and come to divergent conclusions regarding the most appropriate course of action. Consider the controversies around the "right to die" near the end of life, often exemplified in discussions about withdrawing or withholding treatment, palliative sedation, or medical aid-in-dying. One can readily identify tensions among the core bioethical principles in such issues; wherein reasonable people might disagree about how to best respect autonomy, balance obligations to beneficence and nonmaleficence, and even address concerns about justice. Some of these tensions are brought to light in the following case:

Sylvia is a 68-year-old woman with advanced chronic obstructive pulmonary disease, a history of breast cancer, and major depression. Though she lives alone, over the past year, she has found it increasingly difficult to maintain her independence: she's been in and out of the hospital several times, and after the most recent hospitalization, she was discharged to a nursing facility for rehabilitation. She found the brief stay in the nursing facility to be demoralizing—not so much because of the quality of care she received, but rather because the idea of being dependent on others for her most basic needs ran contrary to her own sense of self-worth. She counts her ex-husband, her daughter, and a former colleague among her closest supports, and she has vowed to them that she would "rather die" than experience "the indignity of wasting away" in a nursing home.

After another hospitalization—the result of yet another bout of pneumonia—Sylvia appears more depressed than usual, and there are some new concerns about delirium. She makes an oblique reference to her psychiatrist, suggesting that she wishes her life were over: "I'm tired of going through this; when will it end? There must be something you can do to help me. . ."

From the standpoint of bioethics, how should Sylvia's doctor respond? What course of action will strike the right balance among the different—and seemingly opposed—obligations? For instance, how should her doctor negotiate the two components of respect for persons (honoring Sylvia's right to autonomous decisions while protecting her in the event that her capacity for authentic autonomous decision-making is diminished due to what may be depression or cognitive impairment)? Further, apart from concerns about autonomy, how should Sylvia's doctor understand "the good" that should be promoted or "the harm" that should be avoided (in order to respect the dictates of beneficence/nonmaleficence) in a case where a suffering patient, near the end of life, desires that her death come more quickly?

Not surprisingly, in medical ward settings, psychiatrists are frequently asked to provide consultation in cases like Sylvia's—to evaluate the degree to which a patient's refusal of potentially life-extending treatment (or, more generally, their desire for hastened death) may reflect a compromised capacity for autonomous decision making due to depression, cognitive impairment, or even psychosis. From the perspective of the geriatric mental health clinician, the question of decisional capacity—a component of informed consent relating fundamentally to the principle of respect for persons—is likely to be instrumental in helping to sort out some of these issues.

Three Components of Informed Consent

The doctrine of informed consent operationalizes the duty to respect autonomy: it ensures that the patient is capable of coupling the physician's expert knowledge with their own personal values and preferences—to arrive at an informed medical decision about their own body. In most formulations, informed consent includes three interrelated components:

1. Voluntariness—Valid informed consent requires that the individual's decision is made in the absence of coercion (i.e., the decision must be truly voluntary).
2. Disclosure—Informed consent also requires disclosure of all the information relevant to the decision at hand, such as the purpose and nature of the proposed treatment or procedure, viable alternatives, and the foreseeable risks and benefits, from each possible course of action (including doing nothing). Such disclosure is generally documented with a printed consent form that the patient or his or her surrogate signs; however, as cogently noted in a report from the Institute of Medicine:

> Conceptually, informed consent should be construed as an evolving decision-making process, rather than as simple "permission." This model of "ongoing conversation and decision making" allows for reinforcement of previously disclosed information, the introduction of new information, and respect for autonomous participant decision making. The act of obtaining *written* consent is tangential to the *process* of informed consent and merely provides a mechanism to document and record that ethically relevant communication has taken place. (Institute of Medicine. Responsible Research: A Systems Approach to Protecting Research Participants. National Academy of Sciences. 2003:108–135. doi: 10.17226/1050.)

3. Decisional Capacity—The individual must have an adequate level of cognitive and reasoning faculty to make an authentic, informed decision.

Four Components of Decision-Making Capacity

Decision-making capacity derives from a set of mental abilities, which together enable a patient to engage in the process of informed consent. Having decisional capacity is a necessary—but not sufficient—element of informed consent. In most formulations, decision-making capacity comprises four conditions:

1. Understanding—the ability to comprehend information relevant to the decision at hand;
2. Appreciation—the ability to apply that information to one’s own situation and condition;
3. Reasoning—the ability to manipulate and consider pertinent information so as to rationally assess the different options available; and
4. Communication—the ability to express a stable choice over time.

Many experts draw a distinction between “capacity” (a determination made by a physician) and “competency” (a determination made by a judge), but the two terms are often, confusingly, used synonymously. In general, questions of capacity should relate to specific interventions at a specific point in time (e.g., a trial of dialysis, or surgical repair of an aneurysm, etc.), rather than to a more generalized ability since the capacity required to engage in a simple, straightforward decision may be substantially different from the capacity required to engage in a highly complex or risky decision (or the capacity to decline a highly beneficial, low-risk intervention).

In most states, decisional capacity can be determined by any licensed physician and sometimes also by a small set of nonphysician mental health specialists, such as clinical psychologists. Hence, most consultation requests for “capacity evaluation” can be framed as providing a second opinion when the primary clinician’s assessment is indeterminate or uncertain. In practice, psychiatrists are frequently consulted when serious affective conditions, problems with cognition, or deficits in reality testing are felt to interfere with decision-making capacity.

Capacity determinations are ultimately based on clinical assessment, which is often complemented by an objective measurement of several domains of cognition. Unfortunately, empirical studies suggest poor reliability, even among experienced clinicians, in terms of categorical determinations of an individual patient’s capacity to consent to treatment based on standard clinical interviews. Interrater reliability may improve when the clinicians providing such ratings are given explicit operational guidelines. Several tools have been developed to assist with the assessment of decisional capacity, such as the MacArthur Competence Assessment Tool for Treatment (MacCAT-T), the Capacity to Consent to Treatment Instrument (CCTI), and the Aid to Capacity Evaluation (ACE). The advantages and disadvantages of any instrument should be considered in reference to the specific purpose of the capacity assessment for an individual patient or research subject. Finally, while published reviews and educational resources often leave the impression that capacity determinations are merely a matter of applying certain criteria in the context of a clinical examination, such assessments in complicated cases are rarely straightforward, and they often involve an uncomfortable degree of subjectivity and judgment.

Respect for Autonomy in Patients With Impaired Decision Making

Where does this leave the geriatric mental health specialist when faced with a person like Sylvia, who, in the advanced stage of a progressive and terminal illness, experiencing some form of depression as well as possible cognitive deficits, begins to give voice to a desire to die? If Sylvia has decisional capacity, she might, for example, choose to decline antibiotics for the pneumonia and be discharged home with hospice care, with an expectation that she would soon die. If she lacks capacity, however, should antibiotics be given without her consent? Should she be “forced,” against her objections, to return to a nursing facility? If she is depressed, should her tiredness with living trigger the standard mental health safety protocols: an evaluation for involuntary detainment, for example? From the standpoint of bioethics, uncertainty about these questions reflects tensions arising from the dual obligation to respect Sylvia’s autonomy while optimizing beneficence (and minimizing nonmaleficence). Hence, in very practical ways, what is done for (and to) Sylvia will hinge on the assessment of decisional capacity.

Often, a careful and systematic process can help to achieve an acceptable solution, even in some of the most complicated cases. A “process-oriented” solution to this ethically challenging situation might involve thoughtful clarification of Sylvia’s decision-making capacity, as well as a comprehensive assessment of other sources of suffering, close communication and collaboration with family, realistic assessment of prognosis and the effectiveness of treatment, and therapeutic interventions provided in time-limited trials with clear outcomes. In Sylvia’s case, such a process might look like this:

1. Empathic clarification of her request: what, precisely, is she referring to when she says, “I’m tired of going through this…”? What does she have in mind when she says, “there must be something you can do to help me…”? As Susan Block and Andrew Billings have observed: “Most patients, in saying that they want to die, are asking for assistance in living—for help in dealing with depression, anxiety about the future, grief, lack of control, dependence, physical suffering, and spiritual despair.”
2. Attention to potential sources of coercion (e.g., from financial pressures or burdens of caregiving).

3. Careful assessment of decisional capacity. When severe depression influences capacity, it often does so through distorted judgments, leading patients to undervalue the likelihood of a meaningful future, underestimate the possibility that depression could be relieved, or even be unaware of the presence of depression itself.
4. A thorough exploration of Sylvia’s long-held values; how she has made decisions in the past; confirmation from a surrogate that her current choices are “authentic” in the sense that they are in alignment with her lifelong preferences and values.
5. Identification and treatment (if consistent with the goals of care) of any potentially reversible causes of delirium.
6. Thorough, expert characterization and appropriate treatment of “depression.” Is this another major depressive episode? Grief? Demoralization? An adjustment disorder?
7. A comprehensive review of other forms of distress: physical, emotional, interpersonal, spiritual, practical, etc. Reliance on an interdisciplinary team to respond to the patient’s suffering and deliver the plan of care.
8. Interventions that are structured in time-limited trials with clear outcomes.
9. Continuous, frank communication with the patient, her surrogates, and other relevant stakeholders.

Although treatment “against one’s will” is sometimes supported by the obligation to protect vulnerable individuals with impaired decisional capacity, clinicians should also be open to the possibility that, in many cases, one can simultaneously respect the person’s autonomy and dignity while also protecting him or her as a person vulnerable to impaired decisional capacity. In particular, efforts to explain and obtain the person’s assent, wherever possible, will foster dignity and respect, even when consent must be obtained from the patient’s surrogate.

Ethical challenges are commonly seen in geriatric psychiatry because advancing age and mental illness can combine in unique ways that undermine autonomy and threaten personhood. When such challenges arise in older adult mental health care, they are often the result of tension between two core ethical principles: respect for autonomy and beneficence. The doctrine of informed consent and the concept of decision-making capacity are two constructs that operationalize the duty to respect autonomy. Some of the most difficult ethical challenges in geriatric mental health can be addressed by adopting a process that optimizes and preserves a patient’s ability to express their autonomy while engaging an interdisciplinary team to assess and address the multiple dimensions of distress that can occur in this population.

55.6d Gender Issues

HELEN H. KYOMEN, M.D., M.S.

Gender and age are important factors in the daily practice and science of medicine and are key components in establishing diagnoses, evaluating risks, and determining treatment, including the safe and effective dosages of medications. Due to differences in life expectancy, there are more older women than men. In 2018, there were approximately 125 older women for every 100 older men in the United States; in those 85 years and older, there were about 181 women for every 100 men. This has significant clinical and scientific consequences. For example, in current psychiatric practice, psychopharmacologic interventions are widely used. In general, prescription drugs are used more frequently by older adult women than men. According to global postmarketing drug surveillance data, overall, women report more adverse drug reactions than men. Yet women, specifically those of older age, were underrepresented in medical investigations. Studies designed to establish the safety, tolerability, and efficacy of medications were historically biased for incorporating younger men as study subjects. As a result, established therapeutic guidelines may have been inadequate or inappropriate for older women.

Great efforts have been made toward filling the knowledge gap that resulted from the historical underrepresentation of women in research studies. In 1985, the U.S. Public Health Service Task Force issued a report on women’s health issues that documented that women were disadvantaged in health care and research. Based on this report, the National Institutes of Health (NIH) released a policy encouraging the inclusion of women in clinical research. In 1990, following an investigative study by the Government Accounting Office (GAO) and urging from the Congressional Caucus on Women’s Issues, the NIH established the Office of Research on Women’s Health to take responsibility for establishing policy and promoting research on women’s health. In March 1993, the U.S. Food and Drug Administration (FDA) stated that it would “end its ban on women’s participation in most drug safety tests and require companies to carry out analysis by gender in virtually all applications for new drugs.” This declaration followed the GAO October 1992 report “FDA Needs to Ensure More Study of Gender Differences in Prescription Drug Testing.” Further guidance was issued in 1993, followed by regulations in 1998 and 2000. Federally funded clinical intervention studies would be required to include women, with data analysis by gender. These legal pronouncements, with continued oversight, help to ensure that women are represented in health care research, which informs current evidence-based medical practice and patient-centered care.

Clearly, patients are better served when gender and age are considered. This is especially important for older women as after menopause, morbidity and mortality from conditions such as cardiovascular disease, major neurocognitive disorder, or depression reach or exceed rates seen in men. These differences will be highlighted and illustrated in the sections that follow.

IMPACT OF GENDER ON PSYCHIATRIC CONDITIONS

Major Neurocognitive Disorders

Major neurocognitive disorders are important health concerns in aging populations. Major neurocognitive disorders due to Alzheimer disease and major vascular neurocognitive disorder together account for over 60% to 80% of all major neurocognitive disorders. Of those diagnosed with major neurocognitive disorder due to Alzheimer disease, about two-thirds are women. Being a woman has been associated with an increased risk of developing major neurocognitive disorder due to Alzheimer disease, although the evidence is not as clear for major vascular neurocognitive disorder. Research using autopsy data suggests that over half of patients with major neurocognitive disorder due to Alzheimer disease have vascular lesions.

There is a growing body of scientific literature on how cardiovascular risk factors may play a role in the development of major neurocognitive disorder due to Alzheimer disease. Obesity in midlife may influence, to a greater degree in women than in men, the development of major neurocognitive disorder. Hypertension and hypercholesterolemia in both women and men predict a higher risk of developing major neurocognitive disorder due to Alzheimer disease with aging. In women older than 75 years of age, rates of hypertension and hyperlipidemia are higher than in men of similar age. Thus, with older age, hypertension and hyperlipidemia may play a more prominent role in the development of major neurocognitive disorder due to Alzheimer disease in women. The apolipoprotein Eε4 (ApoEε4) genotype seems to be a risk factor for major neurocognitive disorder due to Alzheimer disease primarily in women and seems to have a more deleterious effect on hippocampal gross pathology and memory performance in women than in men. Diabetes, which increases in frequency with age in women to a greater extent than in men, is associated with an increased risk for cognitive impairment and may influence this trend as well. Whether prevention or reversal of these associated factors can cause a decreased risk of major neurocognitive disorder due to Alzheimer disease in women has yet to be clearly established.

Women with major neurocognitive disorder due to Alzheimer disease are at greater risk of having comorbid conditions undetected and inadequately treated, potentially affecting mortality risk. In a cross-sectional study of 340 community-dwelling older adults with major neurocognitive disorder due to Alzheimer disease, women were at greater risk of having a malnourished state that was undetected by clinicians, despite having a low body mass index (BMI) (less than 21). In a retrospective cohort study of 5,831 men and 17,918 women nursing home residents with major neurocognitive disorder due to Alzheimer disease, women were underweight, less likely to be hospitalized, and received fewer medications for each disease compared to men. The women in this cohort were also older and more severely cognitively impaired than the men. In an observational study of 28,367 nursing home residents with major neurocognitive disorder due to Alzheimer disease, it was found that although psychotic and depressive symptoms were equally prevalent in both women and men, women were more likely to receive antidepressants and men were more likely to receive antipsychotics. This may be due, in part, to the fact that men were more likely than women to have behavior problems such as wandering, abusiveness, and socially inappropriate behaviors in this cohort. These findings suggest that greater attention by gender to the nutritional, health, and psychiatric status of older adult patients with major neurocognitive disorder due to Alzheimer disease may be needed so that appropriate, timely interventions may be proactively implemented.

As major neurocognitive disorder due to Alzheimer disease progresses, a decline in cognitive, functional, and overall health status occurs, with the gradual loss of the ability to live independently. Women and men with major neurocognitive disorder due to Alzheimer disease, if admitted to a nursing home, seem to have different reasons for nursing home admission. A 2-year, four-wave follow-up study with 573 patients with major neurocognitive disorder due to Alzheimer disease and their family caregivers showed that men entered an institution primarily for medical and caregiving needs, but women, who showed less physical and cognitive impairment than men in nursing home admission, entered due to family caregiving patterns. This suggests that providing additional education and support to affect family caregiving patterns might delay nursing home placement for women with major neurocognitive disorder due to Alzheimer disease.

Mortality rates in older adults with major neurocognitive disorder due to Alzheimer disease are higher in women than in men. In a 15-year prospective epidemiologic study of 1,670 community-dwelling older adult individuals, it was found that having a major neurocognitive disorder due to Alzheimer disease increased mortality risk overall in women but not in men.

Cardiovascular risk factors, the lack of detection and adequate treatment of comorbid conditions, and patterns of family care provided to older adult women with major neurocognitive disorder due to Alzheimer disease may possibly influence mortality. If so, interventions to influence these factors might reduce mortality rates in older adult women with major neurocognitive disorder due to Alzheimer disease.

Depression

Depression in older adults is prevalent and a significant public health problem. It is two to three times more common in older adult women than in older adult men overall. The comorbidity associated with depression in older adult women is significant. Depressive symptoms statistically significantly increased the risk for major neurocognitive disorder in women 85 years and older. The prevalence of generalized anxiety disorder is higher in older adults with depression. In studies with fairly large cohorts, the association of depression with decreased health status, disability, and decreased quality of life in older women is prominent. In a prospective study of 4,657 older adult women, depression, along with underweight status, obesity, and smoking, was associated with the development of frailty. A greater prevalence of depression was found to contribute substantially to greater disability and decreased quality of life in older adult women compared to men in a study of 1,348 older adult patients. In addition, depression, and frailty in older adults, especially in older women, have been associated with an increased risk of death.

In population-based cohort studies, depression was found to be associated with increased rates of hip bone loss and lower bone mineral density (BMD) in older women compared to younger women. Higher rates of hip fracture in older adult women have been attributed to declining bone strength with age; depression may exacerbate this trend by potentially influencing rates of bone loss and BMD. Of note, some antidepressants and antipsychotics that may be used to treat depression may exacerbate bone loss by causing hyperprolactinemia and changes in bone metabolism, leading to bone demineralization.

It has yet to be clearly determined whether preventing or reducing depression might improve the health status, disability, comorbid conditions, and quality of life in older women, or vice versa. In addition, there may be complex, fluctuating, interactive relationships among these factors, so affecting one may or may not clearly lead to an association with decreased depression. In such cases, multipronged interventions that influence all implicated factors together may be most effective clinically.

Depression has been associated with psychosocial and lifestyle features. In a cross-sectional study of 580 geriatric hospital patients, depression was associated with fewer social contacts and support. This association persisted even after adjusting for physical and cognitive impairment and was stronger for women than for men. In a study of 860 community-dwelling older adults from 60 to 96 years of age, decreased depression was associated with both light and strenuous exercise status in both women and men, with light exercise having a somewhat stronger effect on depression in women than in men. These findings, albeit associations without clearly established causality, raise questions as to whether programs that promote social support and light exercise might affect depression even more in women than in men.

Although depression and some associated conditions are more prevalent in older adult women than in older adult men, there are significant adverse comorbid conditions associated with older adult men. Suicidality is associated with depression, and because depression is more prevalent in older adult women than in older adult men, it may be expected that older adult depressed women have higher suicide rates. However, the highest rates of successful suicide in the United States had occurred in older adult white men, possibly due to men using more lethal means in attempting suicide. In a community-based sample of 4,051 older adult individuals, major depression with psychotic features was found to increase mortality risk in both women and men, but milder “neurotic depression” was found to increase mortality risk in men only. Determining why women seem to be more “protected” with respect to these factors might help lead to more effective interventions for both men and women who are older adults and depressed.

Psychosis

In women, the onset of schizophrenia peaks at about age 25 to 30 years, with a second, smaller peak after age 45. In men, the age of onset is earlier, at about 20 to 25 years of age. Psychosis is often considered to be uncommon in older adults without major neurocognitive disorder. However, a 3-year longitudinal prospective cohort study of 347 older adult individuals living in community or institutional settings found that the prevalence of any psychotic symptom was 10.1%, higher than previously reported. Moreover, hallucinations, delusions, and paranoia were each related to an increased incidence of major neurocognitive disorder in older adults aged 85 to 88 years. Hallucinations and paranoia were associated with increased 3-year mortality in women but not in men.

A descriptive, cross-sectional study of 90 outpatients with early-onset schizophrenia and 34 with late-onset schizophrenia found that a greater proportion of women had late-onset schizophrenia compared to men (41% vs. 20%). Women overall had more severe positive psychotic symptoms than men, and women with late-onset schizophrenia seemed to have less severe negative psychotic symptoms than men or women with earlier-onset schizophrenia.

In general, these data suggest that women may be more prone to developing psychosis later in life compared to men and that positive psychotic symptoms are more severe and associated with greater mortality in women than in men. However, antipsychotics are frequently used to treat psychotic signs and symptoms, and the use of these medications may affect mortality rates. Both typical and atypical antipsychotics are associated with a greater risk of death, so cautious use of these medications becomes very important.

Other Psychiatric Conditions

Generalized anxiety disorder is much more prevalent among the older adult population than previously believed. In general, anxiety has been reported to be more frequent in women than in men. Among the older adult population, this trend seems to continue. In one study of 103 older adult individuals with generalized anxiety disorder, women comprised 54% (25/46) of patients with generalized anxiety disorder and 70% (40/57) of patients with both generalized anxiety disorder and major depression.

Regarding bipolar disorder, one epidemiologic study found that older adult patients with bipolar disorder reported having higher lifetime and 12-month rates of alcohol use, dysthymia, generalized anxiety, and panic disorder than those without bipolar disorder. Older adult women with bipolar disorder reported more panic disorder, whereas older men with bipolar disorder reported more alcohol dependence. Much more needs to be understood about anxiety and mania in the older adult population, especially with respect to gender issues, before specific recommendations for treatment can be made confidently. However, if the trend toward more anxiety disorders in older adult women persists, it suggests that the judicious use of antianxiety agents might be especially pertinent for women compared to men.

Deterioration of the quality of sleep occurs in both women and men with aging. However, when women enter menopause, they are at higher risk for even greater disruptions in sleep patterns. Gender-appropriate treatment may include time-limited hormone replacement therapy used in the early stages of menopause.

TREATMENT ISSUES

The management of psychiatric conditions includes psychosocial, behavioral, milieu, and other psychotherapeutic interventions, as well as biologically based treatments such as medication or brain stimulation therapies like electroconvulsive therapy and transcranial magnetic stimulation.

Psychotherapeutic Interventions

When treating geriatric patients, there are unique aspects of transference and countertransference that must be addressed. Older patients may view younger therapists as being like their children and less experienced or knowledgeable about life issues. The older adult may feel more stigmatized at having to seek psychiatric help. Although the therapist's understanding of the older patient's relationships with both parents continues to be important, it may be even more essential to determine what the patient's relationships with children and other mental health professionals have been to effectively treat the older patient. Therapists must pay special attention to their attitudes and biases regarding aging, sexuality, disabilities, losses, and death so that these vital concerns in aging are not avoided, and optimal adaptations can be facilitated with the older adult patient. Ageist and stereotyped views of older adults as "shipwrecks at the end of their voyage—hard of hearing, with low vision, physically disabled, asexual, unattractive, slow, unproductive, and close to death"—deny many older adults the professional psychiatric help they need in a respectful, gender-sensitive, reality-oriented, compassionate, and knowledgeable manner that promotes ongoing growth, development, adaptation, friendship, and enjoyment of life.

Gender-specific developmental theory for later life has not yet been established. However, clinically, eclectic psychotherapeutic techniques incorporating aspects of psychodynamic, cognitive-behavioral, interpersonal, and problem-solving therapy have been found to be useful for older women and men. Individual, couples, family, and group therapies may all be helpful in appropriate situations, and peer support and education are vital.

A psychotherapeutic issue of focus in older adult patients includes the need to adapt to being more dependent than in their younger adult years.

Older women and men who, during their younger adult lives, prided themselves on being self-sufficient and able to nurture others may find dependency on others especially difficult. When assistance with personal care is necessary, older patients may have more difficulty accepting direct care from caregivers of the opposite gender, especially if the caregiver is a son caring for a mother or a daughter caring for a father. Excessive resistance to dependency can result in self-injurious or self-neglectful behaviors. Not wanting to be a burden to others (especially one's children) is a common concern and can often be successfully addressed in psychotherapy by pointing out the vital contributions that the older patient has made to the family over a lifetime. Unrealistic and excessive feelings of entitlement and dependency on others beyond actual need and capacity, often with an excessive focus on losses and somatic concerns, may also require therapeutic attention. The individual etiologies and meaning of such behaviors need to be explored and clarified to patients in a gender-sensitive manner.

Family participation is a vital component of psychotherapy with dependent older adult persons. More women in their advanced years live alone, have more chronic illnesses, and may need assistance from adult children. The readiness for emotional, physical, and, at times, financial commitment to parental caretaking can vary widely among adult children in a family. The skilled and sensitive psychotherapist can assess and effectively distribute tasks and can help families function as a quasi-multidisciplinary team while facilitating access to appropriate community resources. By not assuming that the women in the family will take on all housekeeping and caretaking responsibilities, gender barriers to participating in caregiving can, at times, be overcome. Family involvement in medication management and treatment adherence, as well as many other activities of daily living for the older patient, remains a professional standard in the therapeutic interventions for dependent, frail older adults. Even if professional caregiving services are paid for by insurance, family involvement often is essential for the appropriate access and deployment of such services.

Another psychotherapeutic issue of focus for older patients relates to the developmental phase of becoming a grandparent. This subject needs attention in theory, research, teaching, clinical practice, and policymaking. The stereotyped image of the grandmother as an unemployed or retired babysitter, meal preparer, cookie baker, and ever-available individual has become less and less of a reality. Often, no such expectations are made of the grandfather, whose interest and assistance are often appreciated at whatever level he chooses. Grandfathers, especially when retired, may enjoy the new roles of helper and caregiver in which they may not have participated earlier in their lives. A therapist's role in a grandparent's life can include the resolution of intergenerational conflicts and facilitation of the development of this new and challenging identity. Grandmothers who live alone and at a distance are less likely to have the financial resources to visit other family members than grandfathers or grandparents who live together. Clinical observations have revealed that depriving older women of the opportunity of regular visits with adult children and grandchildren can contribute to depression and considerable distress. Other clinical observations reveal that older parents who survive alcohol use disorders from their younger years tend to get depressed when rejected by adult children who cannot forgive their abusive behaviors from earlier years. This rejection inadvertently leads to a deprivation of the grandparent role.

A third psychotherapeutic issue of focus involves addressing cultural, societal, and economic predicaments that the older adult patient may be facing. The older population includes persons born around the turn of the previous century, as well as those born after World War II. Many members of the aging population came to the United States during various immigration waves. Thus, cultural heterogeneity is vast in both older adult women and older adult men. Intergenerational and gender-based variations in cultural practice and language may lead to conflict, calling for cross-cultural psychotherapeutic intervention.

Older adults have experienced many societal changes in the United States. Gender roles for women have changed from being primarily defined by men in power and authority to being less stereotyped and more self-determined. Yet, it is common knowledge that women who succeed in this male-dominated world, be it in political, corporate, academic, or other venues, often remain in the minority. Most of these women learn the "male rules of the game," and many modify their lifestyles by remaining unattached, delaying childbearing, enduring the trials and tribulations of fertility specialization technologies, adopting children, or having no children. Communication styles, behaviors, and responsibilities within and between genders, families, and generations have changed markedly. Older adult patients may benefit from psychotherapy in dealing with the causes and consequences of these tremendous fluctuations in societal roles and circumstances.

Coping with financial issues, including payment for health care and extended care facility placement, is often a focus of psychotherapeutic intervention for older adults. Money management is becoming more complex. Greater numbers of women rise to this task earlier in life, and more women without experience in financial matters must rise to the task in later life. The economic effects of lower educational levels, traditional work roles, and income discrimination experienced by women in young and middle age become exaggerated as retired women depend on pensions and Social Security derived from preretirement income. Women are about one-half as likely as men to have pensions, and the amount of their pension is one-half as much as that of men. When men die, they are three times as likely to leave an impoverished spouse. Single, widowed, and divorced women often must purchase the in-home care that married men were provided through their spouses. Women live longer, have more disabilities, and live alone more often than men. Thus, they often require the services of nursing homes more than men do. Seventy-five percent of nursing home residents are women aged 65 years or older. Women are four times more likely than men to use Medicaid for nursing home care because of their relative indigent status. Due to relatively low Medicaid reimbursement to nursing homes, these women have little choice in the selection of a nursing home. They must share a room, their beds can only be held for a limited period in case of hospitalization, and medications are often generic. Older men with spouses to look after them at home use more acute care hospital Medicare dollars than women. Medicare does not pay for skilled nursing home care for more than 100 days (with days 21 to 100 requiring a coinsurance payment), only covers rehabilitative nursing home care after a 3-day hospitalization, and provides limited coverage for prescriptions. In the past, Medicare provided only 50% coverage for outpatient psychotherapy visits; with the movement for parity in mental health, Medicare covers 80%. Many managed care companies with Medicare contracts have discontinued care provision for the older adult population, leaving many without continuation of much-needed medical care from their primary care physicians. Education and problem-solving regarding these issues, and psychotherapeutic support that promotes the patient’s psychological strengths and resources, may empower patients to cope with these difficult situations with a greater sense of hope and mastery.

Over the last few decades, online (Internet) computer use has grown in the population in general and may be a source of psychoeducational and peer support for older adults, especially for those who are more isolated. One study of 174 subjects found no significant main effects for gender and online communication and relationship preferences for friends, family, coworkers, or unknown individuals. However, frequent Internet users had higher scores on online communication and relationship building. Another study found that although access to computers was equal for both women and men, in the year 2000, women were 0.7366 times, and in the year 2002, they were 0.5675 times less likely than men to use computers to obtain web-based health information. Yet another study found that in 2012, women used the Internet with greater social motives to search for health-related information, while men were more open to establishing a virtual relationship with a general practitioner.

Psychotherapeutic treatment for family caregivers of frail or disabled older adults is important. Family caregivers often continue to work full-time and may have children for whom they are caring. These caregivers are at times referred to as “the sandwich generation,” caught between the tasks of caring for children and older adults. Many sites of employment continue to be unfriendly or economically unable to provide their employees with assistance with family caregiving. Extended family members, including grandmothers, who traditionally might have been able to provide more care, might be employed and less available to help in child and dependent elder care or need care themselves. Reconstituted families in their second and third marriages are spread thin between children of spouses. The availability and quality of community resources for caregiving have remained inconsistent because of inadequate funding and staffing. The consequences of many of these changes are manifested in the crisis of informal caregiving for older adults who are challenged by mental illness, physical conditions, cognitive disorders, and/or functional deficits.

Pharmacologic Interventions

The complexities of incorporating gender issues are often not addressed in the scientific literature specifically, especially among older adults. However, there has been some research evaluating gender differences in the pharmacokinetics and pharmacodynamics of drugs in animals and younger humans.

Pharmacokinetics. Pharmacokinetic investigations in animals and younger patients have revealed gender differences in various factors that affect drug absorption and bioavailability, drug distribution, metabolism, and elimination. Gender differences have been documented for gastrointestinal motility and metabolizing enzyme effects, but studies have not consistently shown a difference in drug bioavailability between women and men. There are few studies examining differences in bioavailability, and these are generally confounded by variability in other pharmacokinetic factors, such as distribution, metabolism, and excretion. The available evidence suggests that gender-based differences in bioavailability are not clinically significant.

Gender-related differences in drug pharmacokinetics may be due primarily to differences in drug distribution, given that many of the factors influencing the volume of distribution differ by gender. In general, women, compared to men, have a higher percentage of body fat, lower mean body weight, decreased plasma volume, and less organ blood flow, leading to differences in the rate and extent of drug distribution. In women, compared to men, due to differences in body fat, lipophilic drugs may have greater volumes of distribution, and water-soluble compounds may have less. For example, a larger volume of distribution for diazepam has been observed in women compared to men, thought to be due to differences in proportions of body fat and gender-related protein-binding changes.

Gender-related differences in plasma protein binding may lead to pharmacokinetic differences for certain agents. Although albumin levels usually are not affected by gender, endogenous and exogenous estrogens decrease levels of α-1 acid glycoprotein (AAG) in plasma and induce hepatic AAG-glycosylation. Exogenous estrogens also increase serum-binding globulins, such as sex-hormone–binding globulins, corticosteroid-binding globulins, and thyroxine-binding globulins. Variations in levels of such plasma-binding proteins may change the amount of active agent that is available. This may be important to consider when interpreting serum drug levels.

Pharmacokinetic variability is influenced greatly by gender-related differences in drug metabolism. Hepatic drug metabolism is influenced especially by hepatic enzyme activity, as well as by liver blood flow, which is less in women than in men. The cytochrome P450 3A (CYP 3A) subfamily, especially CYP 3A4 in humans, is active in the initial hepatic metabolism of many medications. Other prominent cytochrome P450 enzymes include CYP 1A2, CYP 2B6, CYP 2C9, CYP 2C19, CYP 2D6, and CYP 2E1. Drugs also can be metabolized through intestinal CYP enzymes. The frequency of hepatic metabolizing enzyme variant alleles has been reported to differ among ethnic groups and by gender in younger humans and animals. Gender-based differences in drug levels have been attributed to gender differences in hepatic enzyme activity, which also are influenced by endogenous sex hormone production and hormonal changes associated with exogenous sex hormone use, pregnancy, and menopause. Enzyme CYP 2D6 has been found to be important in metabolizing antipsychotic agents. It has been reported that tardive dyskinesia develops more frequently in Chinese women with schizophrenia than in men due to the increased frequency of defective CYP 2D6 alleles in Chinese women. The activity of the enzyme CYP 1A2 has been found to be prominent in the metabolism of antipsychotics and is higher in females than in males.

Drug excretion usually is through the kidney or the liver. Renal clearance of drugs depends on the glomerular filtration rate, which is directly proportional to weight and thus higher in men than women in general. Gender-related differences in drug renal excretion rates are most likely due to weight differences.

Pharmacodynamics. Pharmacodynamic changes in drug response based on gender have not been as well studied as pharmacokinetic differences. Gender-related pharmacodynamic changes are differentiated from pharmacokinetic effects by showing that a given plasma level of active drug in both women and men does not result in the same pharmacologic outcome.

Many psychotropic medications have been reported to have gender-related modifications in pharmacodynamics. Women have greater impairment of psychomotor abilities from diazepam compared to men. This is thought to be due to heightened diazepam pharmacodynamic sensitivity in women. Compared to men, women show more improvement in psychotic signs and symptoms and greater severity of adverse side effects from typical antipsychotic agents. Further studies need to be done to determine whether these differences are caused primarily by pharmacodynamic or pharmacokinetic processes. Some but not all research suggests that women and men appear to show different effects of various antidepressants, although more work is needed to clarify these findings.

FUTURE DIRECTIONS

The fifth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-5) includes sections on Gender-Related Diagnostic Issues for many diagnoses. Yet, it could greatly benefit from more evidence-based gender- and age-specific data, especially regarding neurocognitive disorders. Incorporating gender into the evaluation and management of psychiatric conditions in an evidence-based fashion is important but extremely complex, given that the differences or similarities in responses and outcomes that are observed between older adult women and men may be due to multiple factors. These factors may be affected by contextual, sociocultural roles and attitudes, genetically based, affected by prenatal hormone organizational effects, related to natural or drug-induced hormone fluctuating activational effects, associated with variable circadian/sleep patterns, or influenced by pharmacokinetic/pharmacodynamic characteristics. In older adults, the sum of these, as well as the effects of aging, may play a role. To evaluate these factors carefully, studies ideally would include standardized psychiatric and functional rating scales that are gender-sensitive and incorporate sociocultural contextual measures (such as those evaluating immigration status, ethnocultural and religious values, family and caregiving roles, employment status, and socioeconomic level), assess genetic factors, have greater numbers of observations to account for potential behavioral fluctuations that may be related to changes in hormone levels and circadian/sleep patterns of behavior, evaluate pharmacokinetic and pharmacodynamic factors using gender-appropriate methods, be prospective and longitudinal in nature, and enroll both women and men in adequate numbers to be able to carry out meaningful comparative analyses by gender. Routinely incorporating functional neuroimaging investigations into descriptive and psychotherapeutic/drug interventional studies also may enhance knowledge regarding gender-based differences and similarities in brain function. Data on outcomes with absolute and proportional indices, sociocultural contextual measures, genetics, pharmacokinetics, pharmacodynamics, adverse effects, dropouts, onset and rates of psychotherapeutic or drug intervention effects, and placebo response should be reported by gender. Such all-inclusive studies are challenging to design, carry out, and complete. Due to constraints in resources, time, subject participation, and other practical considerations that can affect scientific rigor, most studies are planned using partial models, focusing thoroughly on a few aspects of any broadly comprehensive study. Approaches such as study replication/semireplication with the convergence of outcomes and statistical techniques using meta-analysis or physiology-based whole-body population models for assessing the influence of individual variability on the pharmacokinetics of drugs are used to help shed light on complex issues. Still, information garnered from the appropriate analysis of primary data of well-designed, highly powered studies would be most convincing.

The Society for Women's Health Research (https://swhr.org/) highlights many specific alarming gender gaps in knowledge that hinder effective prevention, treatment, and cure for conditions that are prevalent in women. Research, clinical, and educational attention and resources need to be expanded to include the older population in ways that are equitable to their numbers, especially for older women.

Gender-based life-cycle studies, of which Erik Erikson, George Vaillant, and others have been the pioneers, should be carried out simultaneously for women and men, rather than sequentially for each gender, to provide the necessary information regarding which lifestyles and conditions promote or hinder healthy aging for women and men. Appropriate and useful engagement of aging men and women regarding the benefits of rapidly changing information technologies needs ongoing attention and development. As psychosocial processes affect illness outcomes, so does illness affect psychosocial processes. Thus, affective, cognitive, and functional status require routine assessment in primary care, and all medical records from primary care physicians, including gynecologists, need to be available to the psychiatrist before the patient's first visit. The managed care interfaces with necessary state-of-the-art medical and mental health care need serious attention and overhaul. Interdisciplinary work, rather than mental health carve-outs and fragmentation of medical, and mental health care, has been shown to benefit patient care and to be cost-effective.

The caregiving crisis needs major policy attention. Education for all primary care and specialties in age- and gender-sensitive diagnosis and interventions needs to start early in medical school and residencies.

Much progress has been made in promoting gender-sensitive research and the prevention, evaluation, and treatment of illnesses. However, tremendous amounts of work still need to be done to promote a greater understanding of the similarities and differences between genders in older adult patients relative to the description, etiology, treatment, and intervention of psychiatric illnesses and the enhancement of healthy behavior.

ACKNOWLEDGMENTS

The author expresses thanks to Dr. Marion Zucker Goldstein (1932–2019), who graciously invited me to coauthor the original version of this chapter. I would also like to recognize the contributions of Harshita Pinnamaneni, a Tufts University School of Medicine Visiting Student Program fourth-year medical student from Wayne State University School of Medicine in Detroit, MI, who participated in researching topics for this current chapter.

55.6e The Legal and Ethical Analysis of Older Adult Abuse

PAUL RICHARD GREENWOOD, L.L.B. (HONS.), ANSAR M. HAROUN, M.D. (RETIRED), DAVID NAIMARK, M.D., AND ARIANA NESBIT, M.D., M.B.E.

Americans who are 65 years or older are the fastest-growing population in the United States and in much of the developing world. For example, according to Governor Newsom's Master Plan for Aging, California's over-60 population is projected to diversify and grow faster than any other age group. More specifically, by 2030, 10.8 million Californians will be older adults, making up one-quarter of the state's population. The mounting statistics suggest that we are on the verge of essentially becoming a "graying world." Unfortunately, as the population ages, older adult abuse cases have become one of the most common crimes.

In the past, law enforcement has typically minimized the importance of cases involving older adult victims: police officers have tended to stereotype older victims, prosecutors have been reluctant to allow seniors to testify, and judges have underestimated the impact of abuse upon the victim. Within the medical profession, there has been a reluctance to accept that an obligation is owed not only to the older adult patient but also to the community to report suspected incidences of older adult abuse.

Most states have specific statutes in their criminal codes addressing "older adult abuse" crimes. However, few prosecutorial agencies take advantage of such laws, in part because of outdated perceptions about seniors. Some of the classic stereotyping of older citizens portrays them as being senile, fragile, long-winded, grumpy, hard of hearing, and unable to see well. Due to these stereotypes, police officers may write incomplete crime reports when the alleged victim is older adult because of their unfounded beliefs that the victim is incapable of providing sufficient information that could lead to a successful prosecution, that he may not have a reliable memory, that his senses are not adequate, or that he may not be strong enough physically to pursue prosecution. A number of communities have recognized both the failings of such misconceptions as well as the fact that no one discipline will be able to combat escalating older adult abuse alone. In response, many communities have developed multidisciplinary teams (MDTs) to review cases of abuse and consider different perspectives and methods of addressing the issue. Psychiatrists are an essential component of MDTs because they can provide much-needed information on cognitive issues for law enforcement, adult protective workers, and prosecutors.

DEFINITIONS

For the sake of clarity, a few definitions are proposed. There are three general categories of older adult abuse: physical, financial, and emotional/psychological. Within these broad types, there are several other subcategories.

Physical older adult abuse includes assault and battery, neglect, and sexual assault.

Assault and battery are primarily inflicted by either

1. Opportunists who target the older adult in the streets with muggings and robberies
2. Family members (typically children and grandchildren) who wield aggression against the older adult relative
3. Care providers who, out of a sense of frustration, lash out in anger against the victim

A care provider neglects an older adult when he or she willfully or deliberately fails to provide basic services of hygiene, medical support, or nutrition to the victim. The term “willful” encompasses circumstances where a caregiver intentionally “turns a blind eye” to an obvious condition that requires positive action in order to alleviate a situation that is endangering the health of the older adult patient. Examples of neglect include failing to turn a bedridden older adult, causing Stage 4 pressure sores, and deliberately withholding crucial medications resulting in a deterioration in the older adult's health.

Sexual assault typically occurs through force, threats, or deception and culminates in unwanted sexual activity. Such conduct can include rape, nonconsensual kissing or fondling, and the taking of sexually explicit photos or videos of the older adult victim.

Financial older adult abuse manifests in several forms:

- *Theft of property:* Most commonly occurs when a care provider steals personal items such as jewelry and antiques that inevitably wind up in the local pawn shop.
- *Theft of individual checks:* Also most commonly committed by a trusted care provider who rips checks from the back of the victim's checkbook and, when cashed, are typically out of sequence.
- *Misuse of an ATM card:* Most likely to be perpetrated by somebody who has either gained the trust of the victim or has threatened and intimidated the older adult into allowing the perpetrator access to the ATM card.
- *Credit card fraud:* Going beyond just the misuse of personal credit, the perpetrator successfully forges the victim's details into a new credit application that has been obtained without the victim's consent or knowledge.
- *Theft of assets:* Involves large-scale pilfering of assets such as savings accounts, stocks, or real property. Trusted individuals may employ a power of attorney (POA) or quitclaim deed, either of which will be obtained through stealth or intimidation. A POA is a legal document that permits another person to make legal decisions on behalf of the older adult. Depending on how the document is drafted, it may permit the other party to sign checks, open new accounts, or transfer assets belonging to the older adult. A quitclaim deed is a legal document that transfers an interest in real property to another person.
- *Scams:* Today's uncertain financial climate, greater accessibility to victims through the internet, and isolation brought about by the Coronavirus pandemic have created fertile ground for crooks and conmen to target the older adult with a wide variety of schemes. These schemes may include
    - Telemarketing fraud, such as bogus charity schemes, illegal sweepstakes, and false investments.
    - Door-to-door salespeople who convince the older adult victim to pay up-front for labor services such as a new roof, driveway, or other home improvements. These con artists may make off with the up-front money or stay around to bilk the senior out of his or her savings.

  - Thieves pretending to be representatives of utilities or roofing companies or some other trustworthy agency, thereby gaining access to a senior's home with the intention of either stealing what they can or casing the residence for a return visit and a more comprehensive theft opportunity.
  - Con artists exchanging a senior's assets in return for a false promise of "lifetime care." This scam takes advantage of the fact that seniors often fearfully contemplate the future when they may be less self-reliant.
  - Telephone scams involving a caller pretending to be a relative, such as a grandchild, who is in some kind of trouble and needs money.
  - Romance scams where the perpetrator meets a lonely, vulnerable senior through a dating website and then proceeds to persuade the victim to send money.
  - Threatening telephone calls demanding immediate payment with a threat that noncompliance will result in the senior citizen's arrest or a cutting off of the older adult's utilities.
  - Scammers posing as IRS agents who are investigating delinquent tax payments.
- *Emotional/Psychological older adult abuse:* Normally presents as verbal threats by a family member. Psychological abuse may include threats, intimidation, humiliation, or other such degradation. Threats may encompass hints of personal violence against the victim, a loved one, or a pet if the victim fails to deliver on financial "commitments."

NOSOLOGY

DSM-IV-TR contained a section on "Problems Related to Abuse or Neglect," which included a subsection on "Abuse of Adult." This subsection included both physical and sexual but not psychological abuse. The more recent DSM-V renames the section "Adult Maltreatment and Neglect Problems."

Like the DSM-IV-TR, the DSM-V includes Adult Physical Abuse and Adult Sexual Abuse; however, it also adds Adult Psychological Abuse. This change reflects the growing realization that maltreatment may take many forms, including:

- *Physical and sexual abuse:* recognized in both DSM-IV-TR and DSM-V;
- *Psychological abuse:* now recognized in DSM-V; and,
- *Neglect:* which has a DSM-V code for both child neglect and for spouse or partner neglect, but not for adult neglect (where neglect of older adults may be coded).

There remains no DSM-V code for:

- *Self-neglect:* where there is no perpetrator, but the older adult fails to provide for self in a proper manner, thus threatening personal health or safety;
- *Abandonment:* when a caretaker or legal guardian leaves the older adult to fend for himself or herself; or,
- *Exploitation:* where a vulnerable older adult is the victim of some scam, usually material or financial.

FACTORS ASSOCIATED WITH OLDER ADULT VULNERABILITY

Seniors often have psychological and financial characteristics that enable exploitation.

The older adult are likely to have:

- Desirable assets (i.e., money in various forms)
- Legal rights to control those assets through their decision making
- Some impairment in decisional capacities
- Psychological desire to exercise autonomy

Because older adults often recognize their limitations in their cognitive functioning and in their decision-making capacity, they may rely on others to help them make financial decisions.

Older adults often select their advisors based on:

- *Trust:* for example, family members who are trustworthy but not necessarily wise
- *Expertise:* for example, lawyers and financial planners who may be clever but not trustworthy
- *Legitimacy:* for example, individuals blessed by some authority, like a legal guardian or a priest
- *Knowledgeable:* for example, their treating doctor
- *Control:* for example, their caregiver or whoever gives them spending money
- *Charisma:* for example, whoever is able to charm the older adult

The characteristics the older adult choose for an advisor might have no relationship to the moral character of the advisor, who may be determined to promote the interests of the older adult or motivated only by self-interest.

Exploitation is likely to occur when a vulnerable older adult receives financial advice from an individual motivated only by self-interest. Such exploitation may violate the law, ethics, or both. Illegal exploitation is usually easily recognizable because the law is written in language that is precise, with a crisp boundary between what is legal and illegal. It may be more difficult to recognize ethically questionable but legal behaviors as exploitative.

MULTIDISCIPLINARY TEAMS

In recent years, in response to escalating incidents of reported older adult abuse, many communities have developed MDTs. MDTs are comprised of individuals from different disciplines who meet on a regular basis to review cases of abuse and neglect, provide resources and different perspectives on the case, and address systemic problems contributing to the case. Key members of MDTs are representatives from Adult Protective Services (APS), law enforcement, prosecutors, financial institutions, medical examiners, hospital personnel, mental health case workers, the Public Guardian, psychiatrists, and organizations that provide services to older adult community members (e.g., Meals on Wheels). Some states have created MDT teams in order to address specific types of abuse; for example, a Financial Abuse Specialist Team (FAST) or an Older adult Death Review Team (EDRT).

APS is the agency in the majority of states that provides social services to older adults and adults with disabilities. However, unlike their counterpart, Child Protective Services, APS relies heavily on the cooperation of the "client." If the victim refuses services offered by APS, then typically, the investigator has no option other than to walk away and close out the case.

There is no uniform definition of an older adult who falls under the jurisdiction of APS. Some states use age as definitive. For example, California defines an older adult as anyone 65 years of age or older, while Illinois regards an older adult as anyone 60 years or older. In further contrast, Colorado defines an older adult as anyone 70 years of age or older. Other states instead use a variety of definitions, such as "endangered adult" or "vulnerable adult."

Psychiatrists should become familiar with their local APS agency and with their state's definition of "older adult." A useful starting point is to contact the National Adult Protective Services Association (NAPSA). Additionally, an inquiry should be made of the local APS as to whether an older adult abuse prevention MDT exists. Psychiatrists can provide valuable insight at such meetings, particularly when there are discussions about undue influence and consent. Most MDTs have a Memorandum of Understanding (MOU) that clarifies issues of confidentiality and potential conflicts of interest.

An important role of the MDT is to provide ongoing education to professionals about current older adult abuse issues. Special attention should be given to improving interviewing techniques, the importance of photographs and videotaped victim interviews, and spotting red flags and indicators of abuse.

Mandated reporters need to understand their duty to report suspected older adult abuse. There should be ongoing discussions about enhancing or establishing a public awareness campaign that informs the community of the correct channels for reporting suspected cases of abuse. MDT members should orchestrate community efforts to create billboards, posters, and public service announcements on local television and radio. Slogans such as “abuse is getting old” have been found to be an effective means of getting the message out to the public.

The MDT sessions should use every opportunity to educate personnel who deal with older adults in need, such as APS caseworkers, emergency room nurses and doctors, paramedics, and fire officers, in awareness, recognition, and response. Specific educational initiatives may be as follows:

- *APS workers:* After an initial referral is made via a “1-800” telephone number, a caseworker is assigned to pay an unannounced call to the senior. These workers need to be tuned into looking for possible signs of abuse in order that they will know when to bring in law enforcement.
- *Emergency room and other medical personnel:* Sometimes, an older adult patient will appear at a hospital suffering from injuries sustained from an assault or neglect. Medical practitioners need to be able to differentiate between accidental and intentionally inflicted injuries. The victim may be unwilling to explain the cause of such injuries truthfully, and it will be up to the triage nurse to obtain as many details as possible regarding the patient’s living conditions and the events leading up to the patient’s arrival at the hospital.
- *Paramedics and Fire Officers:* These professionals may be the first responders to a domestic call for assistance when an older adult person is in need. If the paramedic is not trained to notice certain indicators of abuse or neglect, police may not be called to the scene.
- *Financial workers:* Financial older adult abuse often occurs at a bank, credit union, or stockbroker firm. The perpetrator will often take the older adult victim into a financial institution in order to prepare a POA or arrange for a transfer of money. The staff at these institutions should be trained to spot various techniques used to exploit seniors. MDT members

dealing with personnel from financial institutions can help alert them to red flags and suggest possible responses. For example, financial staff should make it a policy to discuss any alterations in financial arrangements or substantial withdrawals with older adult customers in private, away from the older adult’s companion. Some states—including Massachusetts and Oregon—have already established such protocols. These protocols provide excellent resources for other states. Several states have also enacted laws that provide immunity to banks when reporting a suspected case of financial older adult abuse to APS or to law enforcement. And some states, such as California, have decreed that any employee of a financial institution is a mandated reporter of suspected older adult financial exploitation. In addition, in recent years, the Security Exchange Commission has approved rules for placing temporary holds on the disbursement of funds or securities where the investment broker believes that the client may be the victim of older adult financial exploitation.

- *Attorneys who provide legal assistance to older adult clients:* Attorneys need to be educated about the signs of dementia and the impact that cognitive impairment can have on the older adult client’s decision-making. Psychiatrists can give valuable insight to these professionals about the need for sensitivity in gauging an older adult’s capacity to make sound legal decisions.

THE RED FLAGS AND INDICATORS OF OLDER ADULT ABUSE

Signs of older adult abuse may be mistaken for the initial symptoms of dementia or merely the result of increasing frailty. For example, caregivers may offer logical-sounding explanations for everything from unusual bruising to abnormally frequent check writing. Although many caregivers are warm, caring, and trustworthy people, professionals who interact with older adults need to examine situations with a keener eye than the general population.

A victim of older adult abuse may become increasingly withdrawn from the community and dependent upon the perpetrator. If an unannounced visit by a caseworker from APS is made, the perpetrator may insist that “this is not a good time.” Excuses might include that the victim is sleeping or is unwell. Even if access is given, the caregiver may try to prevent a private conversation between the victim and the social worker by leaving the door open or by hovering over the victim. Similarly, family and friends who attempt to make telephone calls to or visit the older adult are often prevented from speaking directly to the victim. Alternatively, the perpetrator may monitor the visit or phone call.

Other notable signs of abuse include:

1. Unexplained signs of injury such as bruises, welts, or scars. It is especially concerning if they appear to be symmetrical or shaped like a specific object.
2. Broken bones, sprains, or dislocations.
3. Overdose on prescription drugs or an indication that a medication is not being taken regularly (e.g., a prescription has more pills remaining than it should or remains unfilled).
4. Broken eyeglasses or frames.
5. Signs of physical restraints (e.g., marks around the wrists or ankles).
6. Unaccounted weight loss, signs of malnutrition, and dehydration.
7. Untreated physical problems (e.g., bed sores, urinary tract infections, etc.).
8. Unsanitary living conditions (e.g., dirt, bugs, soiled bedding, and clothes).
9. An unbathed and unkempt older adult.
10. Unsuitable clothes for the weather.
11. Living without essentials (e.g., no heat or running water, faulty electrical wiring, and other fire hazards).
12. Older adult left alone in a public place.

During financial transactions at a bank, the suspect caregiver will often attempt to control the conversation with the bank official and will endeavor to speak on behalf of the victim. The bank clerk may be told that the older adult customer is sick or hard of hearing. The suspect will justify the need for a POA or will insist that any withdrawals are made in cash.

Other financial red flags include larger-than-usual withdrawals, sudden changes in the older adult’s financial condition, items or cash reported missing from the senior’s home, and suspicious changes in wills, POA, titles, and policies. In addition, sometimes names are added to the senior’s signature card, and bills are uncharacteristically left unpaid. There may be evidence of financial activity that the senior could not have initiated because of physical impairments. There may also be contracts for unnecessary services, goods, subscriptions, or evidence of over- or undermedication.

SENIORS AND THE COURT SYSTEM

For many seniors, their own abuse will be their first exposure to the criminal justice system. Because older adults may have fears, misconceptions, embarrassment, and feelings of reluctance about pursuing their case, a treating psychiatrist should discuss such feelings with their patient prior to a hearing where the older adult will be required to testify. With the older adult's permission, the psychiatrist may consider reaching out to the prosecutor or victim advocate prior to the hearing to discuss any major concerns that the older adult may have.

If a question regarding the older adult's competency to testify arises, the psychiatrist should know that the threshold to demonstrate the witness' capacity is low. More specifically, the witness typically only needs to show that he or she understands the significance of taking the oath and is able to appreciate the difference between telling the truth and a lie.

ESTABLISHING A "THEFT" IN OLDER ADULT FINANCIAL ABUSE

It is sometimes difficult to ascertain whether sufficient evidence exists to prove that theft has occurred. In other words, it can be challenging to demonstrate that a suspect has taken property from the victim without consent and with the intent to permanently retain the said property.

Three different scenarios often occur:

Scenario One: The victim is able to testify competently that the defendant took money or property without consent. The victim may be asked to look at a check and confirm that the signature is a forgery or that a series of ATM transactions were not authorized.

Scenario Two: The victim is incompetent to testify because of a severe major neurocognitive disorder. The transaction took place at a time when the victim was already diagnosed with that advanced condition. A treating physician for the victim will need to lay the appropriate medical testimony foundation to establish that the victim would have been unable to provide the necessary consent at the time of the transaction.

Scenario Three: The victim is marginally competent to testify, although there may be some signs of short-term memory loss. The victim appears to have voluntarily transferred assets to the suspect and appears to understand the nature and extent of the transaction. The suspect may describe the transfer as either a gift or a loan. Law enforcement may have refused to investigate such a scenario on the basis that no apparent crime has been committed. The scenario may be further

> complicated by the fact that the victim, prior to the transaction, was taken to meet with an attorney (unsurprisingly, chosen by the suspect) to discuss the impending transfer. That attorney will likely testify that the client understood the significance of the transaction and wished to proceed. This last scenario is the most difficult one to prove as theft, even if the suspect has clearly manipulated the older adult victim to bring about the intended result. Lawyers refer to this conduct as "undue influence."

Historically, the concept of undue influence has been used widely in civil actions such as will contests or contract disputes. However, a growing number of states recognize undue influence as a criminal concept. As a result, creativity is required in order to introduce evidence of manipulation that will demonstrate that the transaction was completed without the victim's consent. Often a psychiatrist can provide valuable testimony either as an expert witness to explain undue influence or as a percipient witness to discuss the victim's susceptibility to manipulation.

Consent is the cornerstone of many financial older adult abuse cases. In California, the trial judge in a criminal financial older adult abuse case can instruct the jury that, in order to consent to a transaction, a person must:

- Act freely and voluntarily and not under the influence of threats, force, or duress;
- Have knowledge of the true nature of the act or transaction involved; and,
- Possess the mental capacity to make an intelligent choice regarding whether or not to do something proposed by another person.

The judge will then conclude, "Consent requires the free will and positive cooperation in act or attitude."

In grappling with the question of whether an older adult was susceptible to undue influence; certain factors should be weighed:

1. The length of the relationship between the victim and the suspect. The longer the friendship, the less likely it is that fraud can be established.
2. The nature of the relationship between the victim and the suspect. If the suspect performed certain services for the victim without any other evident remuneration, an assessment must be made to determine whether the amount of the transfer was a reasonable exchange for services rendered.
3. The spending habits of the victim prior to the transfer. If it can be established that the victim had a history of frugal spending, it might be

possible to show that this particular transaction was completely out of character.
4. The amount of the transfer compared to the residual left for the victim. Sometimes the victim is left with insufficient funds to provide for unexpected emergencies after the transaction has been completed.
5. The documentation that accompanied the transaction. If the suspect maintains that the monies were given in the form of a loan, then it might be expected that supporting paperwork evidencing a loan was drafted at the same time.
6. The question of whether the lawyer who prepared the documentation was introduced by the suspect to the victim.
7. The issue of whether the victim demonstrated any changes in behavior prior to the transaction that might suggest short-term memory loss, confusion, or a decreased ability to rationally weigh the risks and benefits of different decisions.
8. The methods used by the suspect to develop a friendship with the victim. Did the suspect create a false persona to be more interesting to the older adult? Did the suspect gradually isolate the victim from other friendships and family, causing the victim to become increasingly dependent upon the suspect? Did the suspect ply the victim with alcohol to wear down the victim’s defenses?

EXCUSES AND JUSTIFICATIONS IN OLDER ADULT ABUSE

The psychiatrist should be familiar with common reactions to accusations of older adult abuse. The alleged perpetrator may first deny that there was abuse. Because older adult abuse requires some combination of actual harm, intended harm, or bad motive, the alleged perpetrator may argue that these factors are absent. But if confronted with evidence of proven abuse, the perpetrator may employ some excuse or justification.

In an excuse, the perpetrator admits that abuse occurred but should not have. However, the perpetrator explains their conduct with a statement such as the following:

- “It was an accident” (i.e., with no intent to perform the action);
- “It was a mistake” (i.e., the action was indeed intended but executed in some faulty manner);
- “The victim provoked me”;
- “I was impaired” (e.g., tired, intoxicated, overwhelmed); or,

- “Most nursing homes treat their older adults just as I did, so I was following the norm.”

In contrast, if a perpetrator invokes a justification, they allege that, although the abuse was regrettable; given the circumstances, it was the right thing to do:

- “I did provide substandard care (i.e., abuse), but if I had demanded more resources for better care, I would have been fired. If that were to happen, then the nursing home would not have any doctor, so the residents would be without any medical coverage.”
- “Because some substandard medical coverage is better than no medical coverage, given the circumstances, I was justified in doing what I did.”

ETHICAL ANALYSIS OF SUSPECTED OLDER ADULT ABUSE

The Difference between Threats and Offers

Although most people would agree that threats are ethically problematic while offers are ethically acceptable, the distinction may be difficult to see. For example, a child says to his parents, “either leave all of your assets to me in the will, or I will put you in the cheapest nursing home because you cannot take care of yourself.” This is clearly a threat, the child is exploiting his parents’ lack of capacity for self-care, and this may qualify as older adult psychological abuse. In contrast, a child may say to his parents, “if you leave all your assets to me in the will, I will not put you in a nursing home. Instead, I will buy a larger home, and you can live with me in your old age.” Because this is an offer and thereby not exploitative, it likely does not qualify as older adult psychological abuse. Although in both cases, the parents are invited to consider substantively similar deals, in one case, the proposition is manipulative, while in the other, it is not.

The Difference between Shoves and Nudges

An advisor or caregiver should presumably respect the autonomy of the older adult; violating such autonomy is unethical. “Shoving” refers to forcing a decision onto an unwilling older adult and is clearly unethical. However, the ethics of “nudging”—where information is presented in a different manner in order to improve an individual’s decision-making process—remains controversial and depends on whether the nudge applied supports or undermines an individual’s welfare, dignity, and autonomy. Competent older adults should be masters of their own agency, but such agency can be changed, altered, or influenced by reframing information or overcoming queasiness or procrastination.

An example of a nudge is how information may be reframed if an older adult's medical interest would be promoted by taking a first-generation antipsychotic, but the older adult refuses such treatment. If the patient will only consent to medications that help him "relax," the doctor may mention that a specific antipsychotic medication will cause him to feel "mellow." If the patient then consents to take this medication, the patient maintains autonomy. In this scenario, the doctor nudged the patient into taking a beneficial medication by reframing truthful but influential information.

Similarly, if an adult child knows that his parents want to change their will so that he will become the sole beneficiary, but the parents keep postponing the will update due to procrastination, the child may encourage them to do the paperwork by reminding them that it will otherwise be a significant hassle for him to be forced to get his inheritance through probate court. This would be an example of a nudge that promotes the autonomy of the older adult parents by increasing the likelihood that they overcome their procrastination in order to make a decision that is in line with their autonomous wishes and values.

CORONAVIRUS 19 (COVID-19) AND OLDER ADULT ABUSE

Psychiatrists should also be aware that the global Coronavirus Disease 2019 (COVID-19) pandemic has made it significantly easier for perpetrators to commit older adult abuse.

COVID-19 and older adult abuse:

- Older adults have been forced to stay at home, isolated from other family members. The telephone and computer have become their lifelines, and scams have become more common.
- Scams have emerged involving so-called miracle cures for the virus or using the vaccine rollout as an excuse to obtain personal information of the older adult that is then used to commit identity theft.
- APS caseworkers have been unable to make personal visits to new clients where there are reports of alleged abuse. Instead, the initial

assessment is done over the telephone, preventing the social worker from assessing living conditions and the suspected abuser's behavior.

- Some residents in long-term care facilities have been exposed to COVID-19 and suffered an untimely demise because of a failure by the facility to reduce the risk of transmission of the disease.
- Suspects who have been arrested in "nonviolent" financial older adult abuse cases have typically been given a notice to appear in court at a much later date, often months in the future. By the time the defendant faces either a preliminary hearing or trial, the older adult victim may already have died or may be experiencing serious memory problems.
- Defendants who have been convicted of "nonviolent" financial older adult abuse are often granted noncustodial sentences so as to avoid overcrowding local jails.
- Some older American Asians have been subjected to unprovoked physical assaults in the street; such crimes are being described as hate crimes stemming from misguided beliefs about the origins of the pandemic.

CONCLUSION

Over the last few years, older adult abuse has become one of the most common crimes in the United States. The responsibility to watch out for the senior population is a collective one, and psychiatrists will play an increasingly important role in the fight against older adult abuse as the population ages. It is important for psychiatrists to learn how to identify risk factors for and signs of abuse so that older adults will be protected and the abusers held accountable. Psychiatrists should also consider joining local MDTs that develop protocols to combat older adult abuse.

CASES

Profile of a Physical Abuser of the Older Adult

Very often, the abuser of an older adult is the son of a widowed woman. He may be either divorced and has come back to live at home with his mother because of financial pressures borne by the divorce, or he is single and has never left home. He tends to be in his 40s or 50s, while his mother is usually in her mid-to-late 70s. In the majority of cases, the son is lazy and unemployed. He will have used a variety of excuses as to why he is unable to work, and his mother has accepted such excuses. He will be addicted to alcohol, narcotics, or gambling. In order to feed his habit, the son extracts money from his mother. There may come a time when the mother refuses to provide any more money, and this tends to be the flash point for violence. Violence may begin with him breaking objects in the home that he knows his mother values. As the violence escalates, he may grab his mother's arms, shake her, push her into furniture, or throw an object at her. Characteristically, the mother will not immediately call the police, perhaps out of a sense of failure or shame. Often, neighbors hear the altercations between the son and his mother, but they may also be reluctant to involve the police.

Profile of a Financial Abuser of the Older Adult

The profile of the financial abuser is more difficult to describe. The exploiter can be a family member who has been distant for many years and, after the death of the older adult's spouse, surfaces to befriend the widow or widower in the hope of acquiring some or all of the anticipated inheritance. Alternatively, the abuser can be a trusted individual such as the victim's attorney, realtor, accountant, pastor, or physician. Ultimately, many financial abusers will portray the transfer of assets as either a "gift" or a "loan." For that reason, many alleged thefts from older adults are mistakenly judged to be "civil" rather than criminal violations.

Guardianship abuse has gained national attention over the past 3 years after a high-profile case out of Nevada involving defendant April Parks. Parks was a professional guardian appointed by the probate court in Las Vegas to manage and control the finances and lives of multiple older adult clients. She used her position to drain many of her victims' bank accounts and isolate them from their families. In January 2019, Parks was sentenced to 16 to 40 years in state prison. As a result of this case and others like it, many states have begun a process of examining lesser restrictive alternatives to guardianship called supported decision-making. Psychiatrists need to be involved in decisions regarding whether an individual will benefit more from guardianship or supported decision-making.

55.6f Geriatric Psychiatry: Sexuality and Aging

ABESH KUMAR BHATTACHARJEE, M.D., PH.D., NIRAJ K. ASTHANA, M.D., AND DANIEL D. SEWELL, M.D.

The proportion of older adults in the United States is rapidly increasing. Data from the Pew Research Organization and the U.S. Center for Disease Control and Prevention (CDC) reveal that an estimated 10,000 Americans turn 65 years old every day and are joining the pool of over 54 million individuals who are presently over 65. Currently, the percentage of

Americans who are 65 years old or older is 15%. By 2030, when all surviving members of the Baby Boomers cohort will have reached or exceeded the age of 65, this percentage will increase to 21% and by 2060 to 25%. Because of these unprecedented demographic shifts, issues impacting the health and well-being of older adults, including sexual health, are becoming increasingly more important.

Traditionally, aging has been viewed as a period of progressive decline in physical, psychosocial, and cognitive domains, which consequently increase the health care burden and decrease quality of life. This negative view of old age contrasts starkly with the recently ascendant concept of healthy aging or successful aging, which is supported by existing research on older adults who continue to function well and be active, productive, and engaged in life. Self-ratings reveal that successful aging is a subjective perception of an individual's quality of life, which comprises physical, social, and spiritual dimensions. Sexual activity and enjoyment are considered components of these quality of life dimensions, particularly the physical and psychosocial dimensions.

Regardless of how long a person lives, experiencing human closeness and intimacy remains important. Individuals and societies react in a variety of ways to sexual intimacy among older people. Despite the rapid growth of the older population and the aggressive marketing of products aimed at sexual health in later life, sexuality in older adults has received relatively limited research attention. A review of cross-cultural data from 106 traditional societies determined that sexual behavior in older men and women was very common though not invariably observed. For example, 84% of the studies, which included information about sexual behavior in older females, documented continued sexual activity and interest among older females. The authors of this review concluded that the continued sexual activity among older members of many traditional societies and the cessation of sexual behavior among older members of other traditional societies suggested that cultural as well as biologic factors might be important determinants of sexual expression in later life in these societies.

Cultural and biologic factors also appear to be important determinants of sexual behavior in the industrialized world, where many still believe that older people stop having sex or believe that it is dangerous for older people to be sexually intimate. For some, certain cultural taboos from the Victorian era may even today inhibit sexual behavior and provoke both intrapsychic and interpersonal conflict. Older people may internalize the myth of sex in older age being "wrong" or "inappropriate," and some may choose to repress their sexual urges rather than become objects of derision or disapproval (e.g., being considered “a dirty old man” or in the case of women, “a cougar.”)

Fortunately, over the past 60 years, attitudes about later life sexuality have been evolving. Contrary to persistent stereotypes, recent studies have indicated that many older men and women remain sexually active, experience sexual desire, and regard sexual activity as an important aspect of their lives. Moreover, multiple aspects of sexual health in older adults are positively associated with self-rated health and indicators of physical function. The Women’s Health Initiative Study found that activity and satisfaction with sexuality were associated with higher self-perceived successful aging and quality of life. The acceptance of hormone replacement therapy for menopausal and postmenopausal women, the increasing popularity of oral erectogenic agents, the incorporation of “ED” into the common vernacular, and the increasing frequency of examples of later-life sexual intimacy in the media all indicate changing attitudes about sexuality in older adults.

It is possible to live a happy and fulfilling life without sexual experiences. A clinician who is knowledgeable about sexuality in later life and willing to discuss sexuality with older patients has the challenge of creating an open, safe environment for discussion without implying that any problem necessarily exists. Ironically, a therapist who addresses these issues must be aware that the introduction of the topic may be perceived as very helpful or may unintentionally trigger feelings of inadequacy or incompleteness in patients for whom sex never was or is no longer a central part of life. Sexual disinterest is a matter of concern only if a person finds it troubling or if it causes problems relating to others. All things considered, it is better to ask with sensitivity about sexual behavior, listen carefully to determine if sexual problems exist, and remember that whatever reaction ensues will serve as an opportunity for a deeper understanding to develop between the patient and the clinician.

In order to help older individuals who are experiencing a discrepancy between their desire for sexual intimacy and their actual experience of it, knowledge about the following may be useful: (1) the neurobiology of sexual function; (2) the effects of aging on sexual function; (3) the impact of gender and/or sexual minority group membership on later-life sexual health; (4) the recommended guidelines for how to take a sexual history; (5) the types of sexual dysfunction, their causes, including dementia, and their recommended treatments; and (6) the impact of institutional living on sexual expression.

NEUROBIOLOGY OF SEXUAL FUNCTION

Sexuality and the Sexual Response Cycle

The neuroendocrine perspective of sexual behavior can be summarized in a five-component model focused on neurologic and hormonal mechanisms that lead to behavioral and motivational changes during human development. These components of sexuality are sensorimotor (prenatal and neonatal spinal reflexes, such as penile or clitoral erections), valence or salience (sensory stimuli developed in the late juvenile period), attractiveness (a wide range of behaviors intended to increase sexual attractiveness), receptivity (the willingness to engage in sexual activity), and solicitation or proceptivity (the urge to seek out partners). With reproductive maturity, all become tightly coordinated until later in life, when these components may become uncoupled again because of different rates of change associated with aging.

The neuroendocrine model acquires a new level of nuance and complexity when considered through the lens of sociologic and psychological conceptualization of sexual motivation. Historically, the scientific literature tends to consider sexual interest and motivation in terms of desire and arousal and places sexual desire in a nested framework of contexts, from dyadic relationships to communities, to cultures. This perspective on sexual motivation harmonizes well with the Interactive Biophysical Model of Health, which posits that health is a function of biophysical and psychocognitive dynamics between individuals over time.

Various models of sexual arousal and response have been proposed over the past century. Masters and Johnson described four sequential phases to the “sexual response cycle”: excitement, plateau, orgasm, and resolution. Kaplan proposed a triphasic model of sexual response, which highlighted the interdependence of the three components (desire, excitement, and orgasm) and proved to be clinically helpful because the phases correlate well with various common sexual problems. For example, low libido or hypersexuality are problems with Phase I or the desire phase, erectile dysfunction (ED) or dyspareunia are problems with Phase II or the arousal phase, and anorgasmia or premature ejaculation (PE) are problems with Phase III or the orgasm phase. The Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM 5) uses these phases as a basis for classifying sexual dysfunctions.

Critics of more traditional, linear models for understanding the human sexual response have identified certain limitations. The first of these critiques argue that traditional models rely on the assumption that sexual desire is fundamentally spontaneous and automatic, which may not accurately describe the sexual experience for many women and may unnecessarily pathologize normal female sexual behavior. For example, it is not clear how the use of this model may have shaped the current view that hypoactive sexual desire disorder is significant among women. One of the more recent refinements of the sexual response cycle has been the addition of the concepts of “spontaneous desire,” which is believed to be more typical of men, and “stimulus-driven desire,” which is believed to be more significant for women and refers to desire aroused by stimuli such as the behavior or appearance of the partner. To build upon this, scholars have also argued that traditional models may not fully capture the role cultural, emotional, and psychological factors and relationship dynamics may play in the human sexual response.

Another concern with the older models is they fail to account for the possibility that normal sexual responses may not always progress in a linear fashion. For instance, in some individuals, arousal or excitement may occur before the development of desire. To address these potential limitations, Rosemary Basson described a nonlinear model, focusing on the female sexual response and capturing the complex biopsychosocial interactions involved. This nonlinear model describes desire as something that is not necessarily spontaneous but, instead, can be generated by both sexual and nonsexual stimuli, such as emotional intimacy, love, and other relational factors. Additionally, while desire can precede arousal, this linear progression is not always required; instead, arousal can precede desire, or sexual stimuli can increase both desire and arousal simultaneously. The nonlinear model also notes that both physical and psychological satisfaction drive emotional intimacy, which in turn may increase an individual’s likelihood of both seeking out sexual stimuli as well as being receptive to them. Since the development of Basson’s nonlinear model, researchers have also noted that, although the nonlinear model was originally developed to address shortcomings associated with describing the female sexual experience, its principles can likely be applied to both sexes. Ultimately, the nonlinear model provides a framework that includes individuals that may not have spontaneous sexual desire and provide a means for understanding additional ways that sexual desire can be developed and interact with other components of the human sexual response, like arousal and stimuli.

Recently, there has been an increasing amount of research using neuroimaging to better understand the neurobiology of sexual function. Functional neuroimaging research efforts looking at the different phases of the sexual response cycle have found characteristic patterns of brain activation during different phases. Researchers have identified that in the desire phase of the sexual response cycle, they see coactivation that is described as a “sexual wanting pattern” and involves activation of the occipitotemporal cortex, superior parietal lobule, ventral striatum (VS), amygdala, hippocampus, orbitofrontal cortex (OFC), anterior cingulate cortex (ACC), and anterior insula. Meanwhile, in the arousal state, researchers have observed what has been termed a “sexual liking pattern” involving activation of the hypothalamus, anterior and posterior insula, ventral premotor cortex, middle cingulate cortex, and inferior parietal lobule. Notably, there are very similar patterns of brain activation across gender groups and sexual orientations, as long as preferred sexual stimuli are used. Additionally, patterns of brain activation observed in these various phases were also found to be stable over time, and even when subjects were scanned a year or more apart, the brain response remained similar. Additional information about the neurobiology of the sexual response cycle can be found elsewhere in this text.

AGE-RELATED CHANGES IN SEXUAL FUNCTION AND BEHAVIOR

Aging may have both positive and negative impacts on sexual expression. Normal age-associated changes in sexual function are summarized in Table 55.6f–1. For women during and after menopause, lowered estrogen levels cause atrophy of the vaginal epithelium, labia majora, and Bartholin glands (the source of fluid that lubricates the vagina), as well as shortening and loss of elasticity of the vaginal canal. Reductions in vaginal blood flow, genital engorgement, and vaginal lubrication lead to a delay in achieving sexual arousal. Loss of lubrication may also contribute to dyspareunia. Notably, over half of postmenopausal women experience a genitourinary syndrome of menopause, which has been found to be one of the most important factors responsible for increasing the odds of female sexual dysfunction.

While orgasmic capacity is retained with age, decreased muscle tone may decrease sensitivity, orgasm may require a longer period of direct stimulation, there may be reductions in the number and intensity of vaginal contractions, and some women may experience painful uterine contractions during orgasm. Moreover, postmenopausal hormonal changes also increase the risk of pelvic organ prolapse, which has been associated with both physiologically and psychologically negative impacts that impair sexual function. In particular, chronic pelvic pain, dyspareunia, reduced self-image, and increased partner avoidance have been associated with pelvic organ prolapse.

Testosterone in the central nervous system influences female sexual behavior. Women experience declines in androgen levels with age, especially between the third and fifth decades of life. To date, scientific support for a direct relationship between reduced testosterone levels and change in sexual functioning in women is inconsistent, but, in general, lowered levels are thought to contribute to decreases in libido, arousal, responsiveness, genital sensation, and orgasm. Some recent research suggests that both estrogens and androgens may work together to enhance sexual arousal and response in women. For example, the administration of estrogen plus small amounts of testosterone to menopausal women may provide greater improvement of psychological symptoms such as a sense of well-being, depression, and fatigue, as well as sexual problems related to the effects of estrogen deprivation on the genitalia, decreased libido, and anorgasmia. Further strengthening the understanding of this relationship, recent systematic reviews of randomized controlled trials have found that, across several studies, transdermal testosterone therapy is associated with increased sexual activity and improved symptoms of sexual dysfunction in postmenopausal women. The authors do note that it is still unclear whether there is a direct relationship between circulating testosterone levels and symptoms of sexual dysfunction and whether the effect of androgen therapy on sexual function may be due to increased aromatization of estrogens.

Table 55.6f–1.
Normal Age-Associated Changes in Sexual Function

Function	Male Changes	Female Changes
Sex hormones	Decline in testosterone levels	Cessation of estrogen production Decline in testosterone levels
Genitals	Fewer and less functional sperm Decreased penile blood flow Decreased penile smooth muscle relaxation	Cessation of ovulation Decreased pelvic blood supply Shortening and narrowing of vagina Atrophy of vaginal mucosa, labia majora, Bartholin glands Decreased vaginal elasticity Decreased muscle tone
Fertility	Reduced rates of conception	Ceases after menopause
Libido	For some, may decline due to lower testosterone	For some, may decline due to lower testosterone
Arousal	Requires more tactile stimulation Erections take longer to achieve Erections are less firm Erections more difficult to sustain	Requires more tactile stimulation Decreased vaginal swelling/lubrication Decreased clitoral sensitivity
Orgasm	Takes longer to achieve Ejaculation is less forceful Decreased ejaculate volume	Takes longer to achieve Fewer, less forceful vaginal contractions
Refractory period	Lengthened by hours to days	Lengthened

Perhaps even more than in men, however, variability of sexual response in women is likely to be contextual, partner-based, and relatively independent of biologic control systems. In general, for women, the response to sexual stimuli is largely influenced by the quality of emotional intimacy with the partner. Frequently, emotional well-being and the health of the relationship contribute more to sexual enjoyment than the physiologic response. Interestingly, recent research assessing the psychobiologic factors involved in sexual function in aging women found that, although aging and menopause were associated with decreased sexual function, the physiologic and endocrine correlates of these processes, including estrogen and progesterone levels, were not predictive of overall sexual functioning. Meanwhile, psychosocial factors, including self-esteem, optimism, life satisfaction, emotional support, and relationship satisfaction, did significantly predict specific important aspects of sexual function, including pain, arousal, contentment, and orgasm.

In men, testosterone is necessary for normal libido and optimal erectile function, and, as in women, testosterone levels also progressively decline with age, particularly beginning around the fifth decade of life, while levels of sex hormone-binding globulin increase. These changes result in more bound testosterone and less free or physiologically available testosterone and are believed to be responsible for the gradual decline in sexual responsiveness in men as they age. Specifically, psychic and tactile stimuli are less effective, and full penile erections occur more slowly. Maintenance of erections also requires more direct genital stimulation. The force and volume of ejaculation may diminish, and ejaculation may not occur with every sexual encounter, but difficulties with rapid ejaculation tend to lessen with increasing age. Other age-related changes include possibly less intense orgasms, retrograde ejaculation, more rapid penile detumescence, and longer refractory periods.

Despite the clear role that testosterone plays in male sexual behavior in later life, the relationship between them remains unclear. For example, the observation that men with a deficiency of testosterone may be capable of an erectile response demonstrates some independence of sexual arousal from testosterone levels and underscores that a lack of sexual interest in men does not result only from a lack of testosterone. As with women, many psychological and relationship factors may contribute to libido in men, such as the perceived level of attractiveness of the partner, various feelings toward the partner such as resentment or hostility, issues related to maintaining control or feeling controlled, and difficulties dealing with sexual dysfunction in himself or his partner.

Research exploring the influence of race, ethnicity, and membership in a sexual and/or gender minority on older adult sexual behavior is emerging but not yet abundant. As a result, available findings should be viewed cautiously. Although supportive scientific information in not yet available, it seems very likely that the psychological factors that contribute to libido in women and men also contribute to libido in those who identify as nonbinary (NB) and who may experience a gender identity that is neither exclusively woman or man or is in between or beyond both genders. It is important to note that some NB individuals may identify as genderfluid, agender (without gender), genderqueer, or something else entirely. Karraker et al. found that in adults aged 57 to 72 years old, non-White and/or Hispanic ethnic status was positively associated with increased sexual frequency in men and decreased sexual frequency in women. Research has also indicated that, in comparison to White individuals, Black older adults may have a higher odds ratio of being in nonmonogamous relationships compared to White and Hispanic groups.

Importantly, across the spectrum of gender and sexual identities, there are a number of chronic medical illnesses that are associated with sexual dysfunction, including Parkinson disease, diabetes, chronic kidney disease, cancer, and cardiovascular disease. Moreover, sexuality in adults suffering from cognitive impairment or dementia is a complex issue that raises important ethical considerations regarding consent and capacity. This is further complicated by the fact that dementia-associated sexual disinhibition can be difficult to differentiate clinically from a cognitively impaired patient's desire to fulfill their sexual needs. Further discussion of this issue can be found in the "Sexual Behavior in Long-term Care" section of this chapter.

Frequency of Sexual Expressions in Older Adults

Until relatively recently, surveys of the frequency of sexual function in later life have, in general, been limited by methodologic short comings such as relatively small, nonrandom subject samples of convenience and questions which narrowly define sex as coitus. In addition, the studies of the effects of aging mainly involve white, middle-class, well-educated, predominantly heterosexual populations, so there is currently much less information about the role that race, culture, sexual orientation, gender identity, education, and socioeconomic conditions play in determining sexuality.

According to several major surveys, 50% to 90% of men and women over 60 continue to be *sexually active*, usually defined as having sexual intercourse at least once in the past year. In surveys of older adults who meet this definition of being sexually active, estimates of their *sexual frequency* have been obtained using multiple choice questions with options such as: once a month, two to three times a month, and once a week or more. Recent explorations of this issue have come from the National Social Life, Health, and Aging Project (NSHAP), which, in Wave 1 of this study, provided researchers with data from a nationally representative probability sample of 3,005 community-dwelling older U.S. adults (1,550 women and

1,455 men) who were 57 to 85 years old, defined sex or sexual activity as "any mutually voluntary activity with another person that involves sexual contact, whether or not intercourse or orgasm occurs," and included in-home interviews conducted in English and Spanish by professional interviewers. Analysis of this data revealed that sexual activity over the past 12 months declined with age. Overall, men were more likely than women to be sexually active, report a good quality of life, and be interested in sex. These gender differences increased with age and were greater among the 75- to 85-year-old group. For men, 84.4% for those 57 to 64, 67.4% for those 65 to 74, and 38.9% for those who were 75 to 85 years old were sexually active, whereas, for women, 61.9% for those 57 to 64, 39.8% for those 65 to 74 and 16.8% for those who were 75 to 85 years old were sexually active.

Wave 2 of this study focused on measuring sexual interest, behavior, sexual experience, frequency, and appeal of physical contact in 3,377 community dwellers who were 62 to 90 years old, and of whom 73.7% (*n* = 2,487) had a spouse or cohabiting partner. It is important to note that 54.8% (*n* = 1,365) engaged in touching the genital organs of their partners. Fifty-nine individuals who were 80 to 90 years old had sexual intercourse in the last 12 months, compared with 383 individuals who were 62 to 69 years old. In general, the measures for the salience/valence and receptivity (terms defined in an earlier paragraph under Neurobiology of Sexual Function: Neuroendocrine Model) components decrease with age. Other noteworthy findings from this study included: the inclination to make one's self sexually attractive to others is stronger in women, two-fifths of the men and women reported dissatisfaction with their partner's frequency of caring behavior that makes later sexual behavior pleasurable, a fifth of women and quarter of men had vaginal sex in the past year, and physical contact is frequent among those living with partners, whereas it is rare among those living alone.

Wave 3 of the NSHAP, completed between 2015 and 2016, provided additional insights into trends in sexual function and behavior among older adults. For instance, analysis of Wave 3 data highlighted the value of affectionate touch among older adults and noted that even nonsexual physical touch was associated with increases in relationship satisfaction, life satisfaction, and mental health for both men and women. Newer studies assessing this data have also looked at sexual well-being in older adults who participate in age-heterogeneous relationships, an area with historically limited literature. Findings from this research revealed that on most measures of relationship well-being and life satisfaction, older adults in age-heterogeneous relationships did not significantly differ from those in age-homogeneous relationships. One important finding, however, was that older women partnered with younger men did have higher odds of reporting an unhappy relationship compared to those in age-homogeneous relationships. The authors theorized that this finding might be due to issues with communication and the increased stigma older women face compared to older men when engaging in age-heterogeneous relationships. Particularly enlightening analysis from Wave 3 of the NHSAP has been that the relationship between quality of sexual life and mental health may be even stronger than previously thought. An analysis looking at data from all 3 waves of NHSAP found that being sexually active was positively related to levels of happiness and general mental health, in addition to being negatively related to levels of depression. Furthermore, higher sexual frequency and better sexual quality were also associated with better mental health outcomes.

The English Longitudinal Study of Ageing (ELSA) provided data on sexual activity and enjoyment of life in a sample of 3,045 men and 3,834 women. Analysis of this data found that for both men and women, sexual activity in the past year significantly predicted a higher mean rating of life enjoyment. Interestingly, this analysis also revealed that forms of romantic or sexual contact other than intercourse, including frequent kissing, petting, or fondling, were significantly associated with higher mean enjoyment of life for both men and women. As the openness and acceptance of the role of sexuality in late life have expanded, the proportion of older adults that remain sexually active may be increasing.

A National Poll On Healthy Aging survey conducted by the University of Michigan/AARP was administered online in October 2017 to a randomly selected, stratified group of older adults aged 65 to 80 (n = 1,002) and provided data on the frequency of sexual behaviors in older adults which was similar to the data from the NHSAP. This study found that 65% of people in this age group described themselves as still being interested in sex, and more than half, 54%, said sex is important to their quality of life. Overall, 40% of 65- to 80-year-old adults are sexually active. The specific percentages by age range were 65 to 70 years (46%), 71 to 75 (39%), and 76 to 80 (25%). Men were more likely to be sexually active than women: 51% versus 31%.

A review undertaken by Beckman et al. (2014) found that the important factors associated with being sexually active at age 70 are: Positive attitude toward sexuality; being married or cohabitating; having a happy relationship; having a partner who was physically and mentally healthy; good physical and mental health; getting good sleep, and drinking alcohol more than three times per week.

Perhaps as the result of biologic factors, social conditioning, or some combination of both, some older people were not especially interested in sex when they were younger, and, even with the increased acceptance of later life sexuality, growing older has not increased their interest. For other older individuals, sexual intimacy has become associated with painful emotional conflict resulting from or causing difficulties with their partners. One member of a couple may have a significantly different level of interest or functional ability than the other. For these individuals, the stereotype of “sexless old age” may provide a comfortable shelter from what is experienced as vexing and/or insurmountable obstacles to the achievement of sexual satisfaction. Still, other older individuals may have simply grown tired of sex and have replaced sexual intimacy with other satisfying nonsexual activities. Some older individuals become celibate as the result of a deliberate decision to share sex only with a single life-time partner who may have become too ill or disabled to have sex or who may have died. The sexual behavior of some older people may be influenced by a religious belief that sex is solely for procreation and, therefore, ends with the completion of menopause. Although it is important to be aware of older people’s sexuality, clinicians must be careful neither to oversexualize the aging process nor to overmedicalize declining sexual function and interest.

Sexually active older adults need and benefit from sex education. Table 55.6f–2 includes strategies for enhancing sexual function in later life. Older adults also need education about HIV and other sexually transmitted diseases (STDs), as well as safe sex practices, including condom use. HIV infection and acquired immunodeficiency syndrome (AIDS) are no longer problems associated only with those who are members of high-risk groups such as gay men, sex workers, and intravenous drug users. Older individuals have also become part of the epidemic, although, fortunately, in the United States, the estimated annual numbers and rates of HIV/AIDS diagnoses in the 65-year-old and older-aged groups have been decreasing. Specifically, according to the CDC, from 2008 to 2018, the estimated rate of new HIV infections among persons 65 years old and older in the United States decreased from 2.4 per 100,000 persons to 1.7. In addition, the number of adults 65 years old and older living with HIV infection who had ever been classified as stage 3 (AIDS) decreased from 748 (2 per 100,000 persons) in 2008 to 673 (1.8 per 100,000) in 2012. In terms of racial and ethnic minority differences, individuals who self-identify as Black/African American or White continue to rank highest among racial and ethnic minorities in terms of the numbers diagnosed with HIV infection and with AIDS.

Table 55.6f–2.
Strategies for Enhancing Sexual Function in Later Life

Optimize Your Physical Health

Maintain a heart-healthy diet

Get sufficient rest

Have your hearing evaluated and corrected if necessary

Learn and practice good dental hygiene, which includes flossing and seeing a dentist on a regular basis

Take good care of your skin

Avoid tobacco products

Minimize alcohol intake

Engage in regular physical exercise

Learn and perform specific exercises that can improve your appearance and function such as crunches and knee raises for a protruding abdomen and Kegel exercises for weakened pelvic muscles

Obtain optimal treatment of any medical illnesses

Inform the clinicians who prescribe medications for you that you wish to avoid medications that are likely to cause problems with sexual function

Pretreat symptoms of pain or dyspnea that interfere with sex

Use lubrication to counteract vaginal dryness and sensitivity

Optimize Your Psychological Health

Foster a positive attitude toward sexuality in later life

Put aside unrealistic expectations of sexual performance

Optimize the Health of Your Relationship with Your Sexual Partner

Maintain open, honest communication

Identify and discuss changes in sexual function

Discuss ways to adapt sexual practices to these changes

Focus extra time and energy on sensual foreplay

Select sexual practices and positions that account for declines in strength and endurance

Recently, there has also been increased research interest in the effects of ageism on sexual function in older adults. Ageism, or age discrimination, has been found across numerous studies to have negative impacts on older adults' self-image, level of emotional distress, and overall psychological well-being. Ageism may negatively impact sexual function and behavior by promoting the internalization of negative stereotypes about older adults.

Mainstream culture can depict older adults as asexual, less sexually desirable, or as impotent. Older men may face negative stereotypes about being “dirty” if they retain an interest in sexual activity as they age or no longer being masculine enough to be considered sexually desirable. Older women may also face stereotypes about sexual activity being “inappropriate” after a certain age, as well as discriminatory attitudes about no longer being sexually attractive enough. Interestingly, a recent study in 2020 assessing public views among younger to middle-aged adults about late-life sexuality found that roughly half of participants (48.9%) held overall negative views of late-life sexuality, confirming that there still exists significant ageism in how sexuality in older adults is viewed. Clinicians also appear to be at risk of ageism biases. Multiple studies have shown that health care professionals are generally less likely to discuss sexual health issues with older adults, which in turn can decrease the chance of older patients seeking help for these issues. Additionally, it has been found that this decreased engagement with older patients about sexuality may be driven by stereotyped views of aging adults, like the belief that sex was less relevant or less important in the lives of older adults. Research findings indicate that older adults who have not had sex in the past 2 years, or were not sure about their hopes or plans for sex in the future, were more likely to have experienced episodes of ageism.

Importantly, as internet and social media technologies have continued to evolve over time, the use of these technologies among older adults in relation to sexual function and behavior has continued to develop. Overall, scientific literature in the area of internet use among older adults is currently limited but growing gradually. Recent research has found that older adults are using the internet for a variety of functions related to sex and relationships. In a recent study of European adults ages 60 to 75 years old, researchers found that 36% of men and 15% of women reported using the internet for sex and love purposes, including watching pornography, finding committed partners, and seeking information or advice. Beyond this, research has also found that internet use can increase the perception of social support in older adults by making it easier to stay in touch with friends and family.

GENDER AND SEXUAL MINORITIES IN LATER LIFE

Terminology and Demographics of the Older LGBTQ+ Population

In an ongoing effort to include all gender and sexual minorities under one umbrella due to their shared formative experiences of discrimination and victimization, the term LGBT continues to expand and evolve. A more recent version of this term is LGBTQ+, where the “Q” stands for questioning or queer, and “+” represents all those who do not identify with any of the groups explicitly included in this initialism (e.g., intersex, asexual, ally, pansexual, agender, gender queer, bigender, gender variant, and pangender). When the “Q” is used to denote questioning, it refers to individuals who remain uncertain of their sexual orientation or gender. In some instances, the “Q” is used as a short-hand for “queer,” which historically has been a pejorative term for gay but which is now reclaimed by some gay men, lesbians, bisexuals, and transgendered persons as a self-affirming umbrella term. In this manuscript, the term LGBTQ+ will be used unless the referenced information relates specifically to a subset of the groups represented under the LGBTQ+ umbrella. Keeping the geriatric theme of this chapter in mind, the authors recommend caution when using the term “queer” when caring for older adults because this term may still be experienced as offensive when used as an epithet, especially among older members of a gender or sexual minority group.

For a variety of reasons, obtaining an accurate count of the number and proportion of individuals who belong to one or more of the gender and sexual minorities has been challenging. The three main sources of information about the size of the LGBTQ community are the U.S. Census, research efforts by individual researchers and academic institutions, most significantly The Williams Institute at the UCLA College of Law, and surveys conducted by the Gallup organization.

Every 10 years since 1790, the U.S. Census Bureau (USCB) has counted everyone who lives in the country, as required by the U.S. Constitution. The USCB collects basic information, including age, sex, and race, for every person. The U.S. Census Survey currently contains questions about a person’s sex, race, ethnicity, and age, but not about their gender identity or sexual orientation. Some helpful information about the LGBTQ+ community became available after The American Community Survey (ACS), a U.S. Census project, began counting same-sex households in the 2005 survey. In 2016, four federal agencies (the Department of Justice, the Department of Housing and Urban Development [HUD], the Department of Health and Human Services, and the Environmental Protection Agency) requested that the USCB include questions about gender identity and sexual orientation in the upcoming 2020 Census Survey to support the efforts by these agencies to prevent or prosecute hate crimes and reduce discrimination in housing, employment, and lending. Although initially approved by the Obama Administration in 2017, the Trump Administration ordered the Justice Department to reverse this decision. The 12-question 2020 U.S. Census Survey asked respondents to identify themselves as either “male” or “female,” which left no accurate option for individuals who are NB and do not identify as either. In June 2021, The LGBTQ Data Inclusion Act (H.R. 4176) was introduced into the House of Representatives. This act would require Federal surveys, including the U.S. Census, to include voluntary, confidential self-report questions on gender identity and sexual orientation. Although support for the LGBTQ Inclusion Act has been increasing, whether it will be enacted by Congress is uncertain.

Although the U.S. Census does not yet ask about gender identity (or sexual orientation), in 2010, a measure of married versus unmarried households was added. For the 2019 ACS and the 2020 Census, the USCB revised the household relationship question. The relationship question in these surveys asked couples living together to define their relationship with their partners in a new way—“same-sex” or “opposite-sex.” The new response categories are allowing the USCB to better understand the characteristics of same-sex households, including their number and geographic distribution, which will help produce the most comprehensive and accurate national data yet on same-sex couples, which can then be used to better inform public policy affecting LGBTQ+ people. Unfortunately, this improved methodology will not provide the number of LGBTQ+ individuals who are living alone or who are not in a relationship, nor will it provide the number of individuals in each of the groups signified by the initialism.

Data collected by the USCB has already begun to create a better understanding of the lives of same-sex couples. Contrary to the long-held societal belief that older members of the LGBTQ+ community are destined to be single, lonely, and unhappy, many have long-term relationships, are emotionally stable, and may be just as likely (or as unlikely) to be successful and happy in their later years as heterosexual individuals. There were almost a million same-sex couple households in the United States in 2017, and just over half (51.7%) of them were female-coupled households. Same-sex households make up 0.8% of all U.S. households, but some cities, such as San Francisco, have a higher percentage of same-sex households—3.0%—than the national rate, according to the ACS. The geographic distributions of same-sex households vary geographically. Interestingly, while there are slightly more female same-sex couple households in the United States, male same-sex couple households are more common in cities with the most same-sex households. For example, about 77.4% of Washington, D.C.’s same-sex households are male, compared to only 56.4% of those in Phoenix. Compared with opposite-sex couples, same-sex couples are more likely to have higher incomes, have both people employed, and be more educated.

For the first time in 2019, the Current Population Survey's Annual Social and Economic Supplement from the USCB's America's Families and Living Arrangements table included estimates of same-sex couples. At that time, there were 543,000 same-sex married households and 469,000 same-sex unmarried partner or cohabiting households. That's a small number compared to the 61.4 million opposite-sex married and eight million opposite-sex unmarried partner households. In addition, there were 191,000 children living with two same-sex parents.

As has been the case for the USCB surveys, until very recently, most scientific studies did not include NB gender or sexual orientation as demographic variables. The consistent inclusion of NB gender and sexual orientation options in future large-scale research efforts will contribute to a more detailed and accurate understanding of the LGBTQ+ population, including those who are older. In addition, there is growing awareness that the LGBTQ+ community is not monolithic, and, as previously noted, separate information about each gender and sexual minority group is needed. For example, to date, no *nationwide* survey has attempted to enumerate the older transgender community.

Another challenge has been determining how best to ask about gender and sexual and minority status. Some experts have suggested that asking about behavior (e.g., With whom have you had sexual intimacy?) rather than identity (e.g., Are you gay?) may provide more accurate information. By far, however, the most common methodology has been self-identification which depends on the perception that honestly answering is safe and will have no negative consequences. Another methodologic concern is the impact of age on a respondent's candor. Older members of the LGBTQ+ community lived through a more intensely homophobic era, may have more internalized homophobia, and may be significantly less likely to feel safe answering questions about their gender and/or sexual identities. For example, 6.5% of the individuals aged 65+ who responded to a 2012 Gallup poll either refused to answer the question about sexual orientation or stated that they did not know. It seems likely that the response rates from studies that use self-identification may underestimate the number of older LGBTQ+ individuals. As more people believe that it is safe to answer questions about sexual orientation and gender identity on large surveys, the percentages will likely increase. Fredriksen-Goldsen and Kim (2014) published a recent study that points to an increasing willingness among older adults to self-identify as LGBT on surveys.

Other than the U.S. Census, a 25-year review of the literature undertaken by Fredriksen-Goldsen and Muraco (2010) revealed that prior to 2000, information about LGBTQ+ adults came from small research studies, all of which employed self-selected samples. The first large-scale research study to include a question about sexual orientation was the inaugural California Health Interview Survey (CHIS) of 2001, and, for the very first time, the 2015 CHIS survey added a question on gender identity. In 2005, scholars at The Williams Institute at the UCLA College of Law began publishing analyses of the data from the USCB and the ACS. Subsequently, The Williams Institute has become the epicenter of LGBTQ+ demographic research.

In 2012, when the nationwide Gallup Poll added a question about sexual orientation (“Do you personally identify as lesbian, gay, bisexual, or transgender?”), 3.4% of the over 120,000 individuals responded that they were LGBT. The Gallup organization has continued to study the LGBT population. In 2017, Gallup estimated that 4.5% of U.S. adults identified as LGBT. In 2020, when the Gallup organization undertook its most recent effort to quantify the size of the LGBT population, the question used was expanded from two options (straight or LGBT) to five options: straight or heterosexual; lesbian; gay; bisexual, or transgender. This survey found that 5.6% of U.S. adults identify as LGBT, with 3.1% identifying as bisexual, 1.4% as gay, 0.7% as lesbian, and 0.6% as transgender.

Research that extends beyond just the quantification of the size of the LGBTQ+ community and includes information about variables such as their sexual behaviors, health, education, occupations, and families has the potential to amplify our understanding of the lives of older LGBT individuals. Beginning in 2005 with The National Social Life, Health and Aging Project (NSHAP), some reasonably sound scientific data about the lives of older LGBT individuals have been published, including information from the National Health Interview Survey (NHIS), the National Survey of Sexual Health and Behavior (NSSHB), and the Aging and Health Report (also known as The Caring and Aging Project) which was launched in 2010 and has yielded the largest sample to date of older LGBT adults, (n = 2,560, aged 50 to 95). The 2013 NHIS, which included 34,557 adults age 18+, was the first large health survey that asked a question about sexual orientation. While the number of individuals in the LGB group was too small (n = 795, 2.3%) to obtain statistically significant results, the LGB group members did show greater rates of cigarette smoking and alcohol consumption and higher levels of psychological distress than their straight peers.

Generational Differences and a Brief Review of the LGBT Equality Movement

People are shaped, in part, by the defining cultural mores and social climate of their formative years. The current population of older LGBTQ+ adults is composed of three generational groups, and each of these groups experienced distinctly different cultural conditions. Those born between 1910 and 1925 (currently 95 years old and older), the “Greatest Generation,” grew up in a world where public or private same-sex behaviors could result in being arrested and sent to prison and hiding one’s sexual orientation was considered self-protective. Those born between 1926 and 1945 (currently age 76 to 95 years old), the “Silent Generation,” came of age in the same repressive environment but witnessed and participated in the social upheavals of the 1960s and 1970s. In 1948, Alfred Kinsey and his associates published *Sexual Behavior in the Human Male*, which was widely discussed by the public, and purported that 10% of adult males in the U.S. were exclusively homosexual. Those born between 1946 and 1964 (currently 71 to 57 years old), the “Baby Boom” generation, lived through their teenage and young adult years at the same time as the “Gay Rights Movement” was born. The Aging and Health Report provided examples of how age/generation impacts the experience of older LGBT adults. For example, data from this study indicated that, among older LGBT adults, the rate of victimization increases with increasing age, and the rate of internalized stigma for those 80 and older is higher than for those 50 to 64 and 65 to 79.

The “Sexual Revolution” of the mid-1960s to 1970s affected both heterosexuals and those who were not heterosexual. The Gay Rights Movement began in the early 1970s and grew into a powerful force pushing for civil protections. One result of this push was the decision in 1973 by the American Psychiatric Association (APA) to remove “Homosexuality” from its list of mental disorders. The evolution of social attitudes toward LGBTQ+ people born during the “Sexual Revolution” began to evolve with unprecedented speed in the early 2000s. In 2003 the U.S. Supreme Court struck down the remaining laws against sodomy in 14 states (Lawrence v. Texas), decriminalizing male same-sex behaviors. Subsequently, one-by-one, states began to legalize same-sex marriage or civil unions. The rapid shift in attitudes towards same-sex marriage resulted in landmark decisions by the U.S. Supreme Court in 2013 (United States v. Windsor) and 2015 (Obergfell v. Hodges), which made same-sex marriage legal throughout the United States.

The current older generations of the LGBTQ+ community grew up during a time of pervasive homophobia, heterosexism, and associated discrimination and hate crimes. Before the turn of the twentieth century, few LGBTQ+ individuals had any sense of connection to others like themselves or acceptance by society at large. Most ended up marrying opposite-sex partners and either lived double lives or suppressed all homosexual sexual inclinations. Not until the Stonewall riots in 1969 gave birth to the modern gay liberation movement did the LGBTQ+ community begin to develop a sense of solidarity and systematically begin to pursue greater social acceptance. As a result, many older LGBTQ+ individuals have endured major traumas personally, politically, and socially. Many older LGBTQ+ couples are still living completely or partially in the closet. The complicated challenges of the AIDS crisis have, in some ways, both helped and hindered efforts to increase acceptance and have diverted both attention and resources away from other important issues which impact the LGBTQ+ community, such as cancer research.

The majority of potential challenges faced by older LGBTQ+ couples are identical to those faced by older heterosexual couples, but a few of the challenges may be different. The key unique challenges for older LGBTQ+ individuals are:

1. A lifetime of discrimination, especially in housing and employment, and a long-term lack of legal and social recognition combine to create deep economic insecurity for LGBTQ+ older adults
2. A reliance on chosen family, due to family rejection and legalized discrimination, creates social isolation and vulnerability, and
3. Long-term discrimination, combined with a lack of competent, inclusive health care, leads to specific mental and physical health disparities.

An older member of the LGBTQ+ community may experience a lack of support from friends, relatives, neighbors, and coworkers, as well as various obvious and subtle forms of discrimination from hospitals, various levels of government, and other institutions such as insurance companies, home health care agencies, hospice organizations, proprietary residential care (PRC) providers, and faith-based organizations. This isolation and unequal treatment can become particularly difficult when a partner is ill or dies. Some of the legal hurdles were mitigated in 2015 by the U.S. Supreme Court, which legalized same-sex marriage in all fifty states, and required states to honor out-of-state same-sex marriage licenses. This decision has helped eliminate forms of discrimination and unequal treatment in a variety of situations, such as hospital visitation, income tax benefits, insurance, retirement benefits, and inheritance. Though the legal rights of LGBTQ couples in same-sex marriage are set clear, the consistent enforcement of these rights is uneven. In addition, other civil rights of LGBTQ+ individuals remain unclear and/or unprotected in some states.

A number of organizations now exist which may provide support and guidance to older members of the LGBTQ community. The existence of these organizations may be especially important for anyone who begins the process of *coming out* as an older adult. *Coming out of the closet*, or simply *coming out*, is a figure of speech for self-disclosure of belonging to sexual orientation or gender identity minority group. Framed and debated as a privacy issue, coming out of the closet is a multifaceted experience in which each person may have both shared and unique experiences. Established in 1978, Senior Action in the Gay Environment (SAGE) is the country's largest and oldest organization dedicated to improving the lives of LGBTQ+ older adults. SAGE offers a variety of social services to older members of the LGBTQ+ community and has independent affiliates in various cities in the United States and Canada. The Lesbian and Gay Aging Issues Network (LGAIN), which is sponsored by the American Society on Aging and the National Association of Lesbian and Gay Gerontologists, has created a resource guide for older LGBTQ+ people. In addition, LGBTQ+ community centers around the country often sponsor or support social organizations for older members of the LGBTQ+ community. For example, in San Diego, California, the LGBTQ+ community center supports a social organization for older members of the LGBTQ+ community called Fellowship of Older Gays (FOG).

HOW TO OBTAIN A SEXUAL HISTORY

Knowing how to take a sexual history is the first step in helping an older person with their sexual quality of life. Many patients think that all clinicians, including psychiatrists, are knowledgeable, skillful, and interested in addressing sexual concerns. Unfortunately, education in human sexuality and on how to take a sexual history is not always emphasized in the curriculums of institutions that train health care professionals, including medical schools and residency training programs.

Though the ability to take a sexual history is not especially difficult to master, doing so may provoke certain fears such as:

1. the clinician or patient experiencing arousal while talking about sex

2. not knowing what questions to ask or how to help with a patient's sexual problems
3. unexpectedly becoming aware of one's own sexual concerns
4. having the patient see one's moral repugnance or personal distaste about certain sexual practices
5. fearing that questions about an individual's sexual health may be experienced as intrusive, inappropriate, or disrespectful, especially when caring for an older adult

   These apprehensions will be reduced by:
    a. identifying them in yourself
    b. thinking about them rationally
    c. learning about the broad range of sexual expressions
    d. understanding professional boundaries
    e. acquiring more knowledge and experience regarding the diagnosis and treatment of sexual dysfunctions; and
    f. increasing one's experience with collecting the sexual histories of older adults (i.e., practicing).

Lindau and colleagues, in 2007, reported that the prevalence of discussing sex with a physician since age 50 for men and women was 38% and 22%, respectively. Other recent research has found that psychiatrists are less likely to obtain a sexual history from older patients presenting with depressive symptoms compared with younger patients, and they are also less likely to refer to appropriate services if sexual dysfunction is identified. On the other hand, many older people are reluctant to seek help for sexual problems even if they have a significant effect on their quality of life.

The evaluation of the sexual functioning of an older individual is like the evaluation of a younger adult, although for the younger clinician, it may be more difficult due to ageist beliefs or fears of offending. General considerations include:

1. establishing rapport which may require that this topic not be explored until at least the second or third contact
2. meeting in a private and comfortable environment
3. introducing the topic by putting it in context (e.g., sexual behavior is both an indicator of health and a contributor to health)
4. intentionally asking patients for permission to talk about their sexual health
5. accepting that the first few times you introduce the topic, you may feel uncomfortable and may even blush but not let this stop you

6. being aware of your own potential prejudices and subconscious feelings
7. regardless of the age of the patient, remember that you are a trained medical expert and may have helpful knowledge to share
8. not waiting for the patient or patient’s partner to introduce the topic because they may assume that you are only interested in “medical problems” or may view sexual problems as trifling (individuals caring for a partner with dementia may be especially prone to make this assumption because of fears that asking about sex may portray them as selfish or as inadequate caregivers with misplaced priorities)
9. beginning with a neutral, nonjudgmental statement like “Have you experienced any changes in your sexual life?” or, when the older individual is being assessed for depression, “sometimes when people feel very depressed, they lose all interest in sex. Do you think this is an issue for you?”
10. using open-ended questions and active-listening techniques
11. demonstrating sensitivity to the patient’s values and beliefs
12. allowing sufficient time for discussion, which means bringing up the issue no later than the midpoint of the time period set aside for the meeting
13. not making assumptions like the person is heterosexual (perhaps as few as 10% of older persons are questioned about their sexual orientation) or that the person has a sexual problem
14. being clear that sexual activity includes both coital and noncoital behaviors
15. providing information about HIV and other STD), including the fact that condom use not only prevents conception but also prevents transmission of STDs
16. educating patients regarding age-related changes that may affect sexuality, like “often women around the time of the menopause can suffer not only with the hot flashes you have described but also with sexual problems such as vaginal dryness. Is that something you have experienced?” or “people at your age may experience ED. Is that something you have experienced?” and, if clinically indicated, discussing noncoital methods of achieving sexual intimacy
17. possibly using humor. (Note: A phenomenologic study with experienced nurses in long-term care found that the use of humor was an effective method of addressing the sexual needs of older adults).

Disclosing sexual history may be particularly sensitive for transgender people because of prior experiences of discrimination in health care. Physicians can ask patients for their gender pronouns simply by inquiring, “What name and pronouns would you like us to use?” or “I would like to be respectful—how would you like to be addressed?” As with all patients, consider assuring transgender people that the questions being asked are important for their medical care and well-being. It is important to avoid assumptions about patients’ sexual orientation or the gender or gender identity of their partners. Transgender people may be of any sexual orientation, and their partners may be cisgender men or women or other transgender people. In addition, as with all patients, it is crucial to avoid assumptions regarding the types of sexual activity (e.g., oral, anal, vaginal, or no sexual activity) in which transgender people engage. Although HIV and other STDs disproportionately affect transgender women compared to other populations, some transgender women may not be sexually active or may be in long-term, mutually monogamous relationships and thus have a low risk of HIV and other STDs. Health care providers should not assume that a patient is at high risk based on gender identity; rather, a risk assessment should be based on each individual’s sexual history.

The CDC has provided guidance regarding helpful questions for discussing sexual orientations and activities, like:

1. What types of sex do you have?”
2. “Have you had any anal intercourse?” If yes, “Was it receptive? Insertive? Was a condom always used?”
3. “Can I ask you a few questions about your sexual partner(s)?”
4. Instead of “Do you use condoms?” ask, “What do you think about using condoms?”; and
5. “Some of my patients find it difficult to talk to a potential sexual partner about HIV. What do you find to be the best way to disclose your HIV status?”

Clinicians taking comprehensive sexual histories serve to enhance the quality of life among older adults by identifying sexual concerns. Sexual dysfunction is common among older adults—approximately 25% for men and 47% for women, especially those with chronic medical conditions. Furthermore, patients prompted by their health care provider are more likely to report issues with sexual functioning, which makes communication with health care providers that much more important.

HOW TO ASSESS SEXUAL DYSFUNCTIONS IN OLDER PATIENTS

Because sexual dysfunction in later life can result from psychological, psychiatric, medical, social, or some combination of these causes, an optimal evaluation should cover each of these areas. For example, psychological factors that impact sexual function in later life include decreased self-esteem or a decreased sense of sexual attractiveness due to physical changes, which may be natural changes associated with aging or changes brought about by illness or the treatment of illness, such as a mastectomy for breast cancer. Sexual dysfunction may also develop when a member of a couple experiences an illness, such as depression, dementia, or stroke, which precludes emotional intimacy. Social issues may also trigger sexual dysfunction. The lifespan of men in the United States is shorter than that of women (75.1 versus 77.8 years), which often leaves older women without sexual partners.

Research has consistently shown a decline in sexual activity with age for both men and women, with the reasons differing by gender. For men, the decline is primarily due to age, poor health, and medications, all of which have been related to ED. For women, health is less of a factor; having a functioning partner is a more important variable. Menopause has some negative impact on women's sexual interests and desires, but psychosocial factors appear to be more important.

In a large recent survey of community-dwelling older adults who were sexually active, about half of both men and women reported at least one troubling sexual problem. The most common forms of sexual dysfunction in older women include female sexual interest/arousal disorder, female orgasmic disorder, and genitopelvic pain/penetration disorder. A 1994 survey, the Massachusetts Male Aging Study (MMAS), revealed that male sexual dysfunction, presenting as ED, diminished libido, or abnormal ejaculation, first emerges as a common problem for men in their early 40s and increases with advancing age. At age 40 years, as an example, 40% acknowledged some level of impaired sexual function, and another 10% recognized a waning sexual prowess or interest with each succeeding decade. The reality is that ED is a natural part of aging, and the prevalence increases with age. In the MMAS, the percentage of participants with ED at the ages of 50, 60, and 70 years were 50%, 60%, and 70%, respectively. Thus, it seems reasonable to conclude that nearly all men who live long enough will likely develop ED. A 9-year longitudinal follow-up study of this same cohort confirmed the age-associated declines in most domains of sexual function: sexual intercourse, erection frequency, sexual desire, satisfaction with sex, and orgasm. Rating one's health as poor was associated with a decreased likelihood of being sexually active and, among those sexually active, being more likely to report sexual problems.

The following are some guidelines on how to optimally assess sexual dysfunction in an older patient. When a sexual problem involves both the person with the dysfunction and their partner, the inclusion of both individuals in the assessment is essential. Often each person will have a somewhat different version of the problem. To initiate the interview, the clinician should ask the identified patient to describe the problem and then ask the partner, "What do you think about this report?" Such open-ended questions can be followed up by more specific questions designed to pinpoint which phases of the sexual response cycle (desire, arousal, or orgasm) are involved for the patient and the patient's sexual partner. Illnesses that cause pain, malaise, or actual physiologic or anatomical limitations may impact any of the phases of the sexual response cycle.

After the joint interview, each person should be interviewed individually. For widowed patients who are in second relationships, it may be difficult to acknowledge in front of the new partner that guilt regarding the deceased partner is contributing to the sexual problem. In fact, the loss of a partner may be the biggest barrier to sexuality for older individuals, especially for older women. Certain societal taboos, though waning, may still prevent a surviving partner from seeking a new mate. Even when a new mate is found, an older person may experience sexual difficulties as a result of guilt arising from a perception of being unfaithful to a former partner and anxiety about overcoming old patterns of physical intimacy and establishing new ones. Masters and Johnson called this "The Widower's Syndrome."

It is essential to learn about the role of sexuality in each person's life and about past sexual experiences. Potentially useful questions include: What would be an optimal frequency for you? Have there been any problems before? What has changed in your relationship? What is the meaning or value of intimacy? Some individuals may view emotional intimacy as an essential precursor to quality physical or sexual intimacy, while for others, the primary value of sex is to assuage libido.

Elucidating the time course of the development of the sexual problem may help uncover underlying etiologic factors. For example, if the problem's appearance coincided with the onset of an illness of the initiation of medication, especially if abrupt, then a causal connection should be strongly considered. Asking a question like "sometimes a person taking these medications notices sexual problems; is this something that has affected you at all?" may be helpful. Many medications, including medications with psychiatric indications like selective-serotonin reuptake inhibitors (SSRIs), have the potential to impact one or more aspects of sexual function.

In general, a gradual onset suggests an etiology related to chronic medical illness. For example, does osteoarthritic pain limit movement or physical position? Does cardiovascular disease reduce physical stamina? Are physical changes associated with aging or illness, such as a colostomy or stress-associated urinary incontinence, provoking embarrassment in the person or impacting sexual interest in the partner? Is a previously unrecognized or unsuccessfully treated psychiatric or substance use disorder present? What is the patient's current sexual ability? It may be helpful to elicit a detailed history of the patient's most recent previous sexual experience. The ability to achieve orgasm during masturbation suggests that the sexual problem may have a psychological origin.

THE TREATMENT OF SEXUAL DYSFUNCTION IN OLDER ADULTS

Just as in a younger adult, sexual dysfunction in an older patient may cause significant distress. The clinician must integrate all of the pertinent information into a compassionate and reasonable treatment plan. If there is a contributing psychological problem, individual and/or couples psychotherapy should be provided. If the sexual problem has a relevant physical or biologic component, then education (e.g., using lubricant to address pain associated with vaginal dryness), medication dose reduction or substitution (e.g., SSRIs), or surgery (e.g., the chronic phase of Peyronie disease) may be helpful.

Desire Phase Problems

The treatment of sexual dysfunctions may be viewed through the lens of the sexual response cycle. The first phase of the sexual response cycle is "desire." Desire may be influenced by psychological, psychiatric, or medical problems. For example, illnesses whose optimal treatment requires surgery may result in physical disfigurement (e.g., mastectomy), which, in turn, triggers low self-esteem and feelings of being no longer sexually attractive or desirable. Psychiatric illnesses which may decrease desire include major depression and alcoholism. Mania is often associated with hypersexuality, and the various forms of dementia may lead to increases or decreases in libido.

A variety of medical illnesses have the potential to reduce libido. One common pathway for certain medical illnesses to trigger decreased libido is a reduction in androgen levels. Illnesses associated with lowered androgen levels include chronic renal failure, chronic pulmonary disease, hepatic cirrhosis, hyperthyroidism, and HIV. Medications such as anticonvulsants and tamoxifen may also lead to lowered testosterone levels. Several medical specialty professional organizations, including the U.S. Endocrine Society, the American College of Physicians, and the American Urological Association (AUA), periodically publish practice guidelines regarding the evaluation and management of male testosterone deficiency. The AUA guidelines emphasize that up to a third of men who are treated with testosterone therapy do not meet the criteria for a testosterone deficiency diagnosis, while a large percentage of men who need testosterone therapy fail to receive it due to clinical concerns about the development of prostate cancer and cardiovascular events, even though currently available evidence does not clearly support these concerns. All of the guidelines emphasize the importance of making a diagnosis of androgen deficiency according to accepted criteria and initiating testosterone treatment only in men with consistent symptoms and signs and two early morning unequivocally low total serum testosterone baseline levels obtained on separate occasions. In some patients, measurement of free or bioavailable testosterone levels is necessary. The initiation of testosterone therapy is recommended for men with symptomatic androgen deficiency to induce and maintain secondary sex characteristics and to improve their sexual function, sense of well-being, muscle mass and strength, and bone mineral density. Testosterone therapy should not be initiated in patients with breast or prostate cancer, a palpable prostate nodule or induration, or prostate-specific antigen serum level greater than 4 ng/mL or greater than 3 ng/mL in men at high risk for prostate cancer, such as African-American men or men with first-degree relatives with a history of prostate cancer without further urologic evaluation, a hematocrit greater than 50%, untreated severe obstructive sleep apnea, severe lower urinary tract symptoms with International Prostate Symptom Score above 19, or uncontrolled or poorly controlled heart failure. Men receiving testosterone therapy should be monitored regularly and require total serum testosterone levels every 6 to 12 months. The panel members who created this guideline favored a cutoff for men of levels less than 300 ng/mL. Finally, the method by which testosterone levels should be measured is an unresolved controversy. The gold standard is equilibrium dialysis, but this test is expensive, labor intensive, and not widely available. Most laboratories measure free testosterone by the analog method, which often yields less reliable results.

The Endocrine Society's guideline for treatment with testosterone is detailed elsewhere in the text (Table 55.6f–3).

Based on currently available data, sex steroids influence female sexual function, but the measurement of androgen levels in women presenting with low sexual function is not helpful and should not be used for the purpose of diagnosing androgen insufficiency in women. Although a recent report suggests that many women following oophorectomy have no decline in sexual function, a subset of women with lowered androgen may experience lowered libido, and there is some evidence that testosterone therapy in this setting may be helpful. A recent review and meta-analysis of testosterone treatment in women provided robust support for a trial of testosterone in postmenopausal women with concerns regarding sexual function. In postmenopausal women, testosterone supplementation improved libido and several other domains of sexual response. For premenopausal women with low libido, the currently available evidence does not support measurement of testosterone serum levels or treatment with testosterone. Currently, there are no approved medications for female hyposexual desire disorder. The Endocrine Society Clinical Practice Guideline reappraised androgen therapy in women after the Task Force established by the Endocrine Society commissioned two systematic reviews of published data and reviewed several other existing meta-analyses.

The Endocrine Society Task Force recommended against:

1. making a diagnosis of androgen deficiency syndrome in healthy women because there is a lack of a well-defined syndrome and data-correlating androgen levels with specific signs or symptoms were unavailable
2. the general use of testosterone for the following indications: infertility; sexual dysfunction other than hypoactive sexual desire disorder; cognitive, cardiovascular, metabolic, or bone health; or general well-being
3. the routine use of dehydroepiandrosterone due to limited data concerning its effectiveness and safety in normal women or those with adrenal insufficiency
4. the routine prescription of testosterone or dehydroepiandrosterone for the treatment of women with low androgen levels due to hypopituitarism, adrenal insufficiency, surgical menopause, pharmacologic glucocorticoid administration, or other conditions associated with low androgen levels because there are limited data supporting improvement in signs and symptoms with therapy and no long-term studies of risk

Table 55.6f–3.
Signs and Symptoms of Low Testosterone

Men
- Erectile dysfunction
- Infertility
- Reduced beard growth

Women
- Impaired arousal
- Decreased genital sensitivity

Both
- Breast discomfort
- Chronic fatigue/lethargy
- Decreased intellectual function, including memory and concentration
- Decreased libido
- Decreased muscle strength
- Decreased physical endurance
- Depressed mood
- Hot flushes, sweats
- Increased fat mass, especially centrally
- Irritability
- Lethargy
- Loss of body hair
- Mild anemia
- Sarcopenia
- Sleep discomfort

Evidence supports the short-term efficacy and safety of high physiologic doses of testosterone for postmenopausal women with sexual dysfunction due to hypoactive sexual desire disorder. Importantly, endogenous testosterone levels did not predict response to therapy. At present, physiologic testosterone preparations for use in women are not available in many countries, including the United States, long-term safety data are lacking, and evidence suggests that transdermal forms of testosterone may be preferred. Any woman receiving testosterone therapy should be monitored for signs and symptoms of androgen excess.

Arousal Phase Problems

Sexual problems in the arousal phase of the sexual response cycle include ED, vaginismus, and dyspareunia. ED is defined as the inability to achieve and/or maintain an erection satisfactory for sexual function. Studies have found that the prevalence of ED is significantly higher among older men as compared to those in younger age groups. The MMAS found a tripling of the prevalence of complete ED among men aged 70 years as compared to those aged 40 years. Compared with men in their 20s, those in the oldest age group (70 to 75 years) had a 14-fold higher relative risk for ED. In this study, age was found to be the strongest predictor of ED. Other age-adjusted risk factors significantly associated with ED included hypertension, diabetes, heart disease, obesity, smoking, hypercholesterolemia, lack of physical exercise, poor health, depressed mood, and prostate disease.

There are now a handful of medications that may be helpful to men with sexual dysfunctions involving the arousal or orgasm phases of the sexual response cycle. Phosphodiesterase V inhibitors act peripherally on the penile vascular system to improve tumescence. These medications increase cyclic guanosine monophosphate (cGMP) in the corpus cavernosum, which relaxes the smooth muscle in the penile vasculature and fosters blood flow. Three medications in this category are now available: sildenafil, vardenafil, and tadalafil, which essentially only differ in their half-lives. Other agents for ED include transurethral and injectable prostaglandin E1, which are less convenient to administer but may appeal to some men who value the immediate and predictable response and who show poor response or intolerance to Phosphodiesterase V inhibitors. Alprostadil, a synthetic form of prostaglandin E1, is currently used, and it has a unique role in men with ED secondary to diabetes and secondary to radical pelvic surgery (e.g., radical prostatectomy).

Orgasm Phase Problems

PE and anorgasmia are sexual dysfunctions of the orgasm phase of the sexual response cycle. Increasing age often diminishes, or sometimes even resolves, problems with PE. The treatment of PE mainly includes drug therapy, which many consider first-line, and psychological and behavioral therapies. SSRIs are effective for the treatment of PE, including fluoxetine, paroxetine, sertraline, and dapoxetine. Dapoxetine hydrochloride is a short-acting SSRI and is the first and only medication approved for *on-demand* treatment of PE in European countries but not in the United States. As treatment with fewer side effects and lower cost, behavioral therapy aims to improve self-confidence and relieve anxiety and depression by continuously training men to master certain sexual skills to delay ejaculation time. In a prospective randomized trial, the combination of dapoxetine with behavioral therapy was more effective in treating lifelong PE patients than the use of dapoxetine alone. Psychotherapy uses counseling to detect and correct any interpersonal problems that can lead to PE. Physical techniques include “stop-start,” “squeeze,” “sensate focus,” and pelvic floor muscle rehabilitation. Studies have shown that the short-term effect of behavioral therapy can reach 45% to 65%, but the long-term effect is still unclear. Finally, there are data that bupropion may have some value for improving sexual function in men. In one study, both normal subjects and patients who took bupropion reported improvements in desire, arousal, and orgasm, and these effects appeared to be independent of antidepressant efficacy.

The definitions of female sexual dysfunction have recently been revised in the DSM 5, with the merging of hypoactive sexual desire disorder and female sexual arousal disorder into female sexual interest/arousal disorder. There are no FDA-approved medications for female arousal disorders or orgasmic disorders. The value of phosphodiesterase inhibitors for women with sexual dysfunction remains unclear. An open-label, nonrandomized study found that sildenafil 50 mg was well tolerated in postmenopausal women with sexual dysfunction and was associated with statistically nonsignificant improvement in vaginal lubrication, clitoral sensitivity, and orgasm frequency, and overall sexual desire or satisfaction with sexual intercourse did not improve. A controlled study of sildenafil 25 or 50 mg as needed found that both doses resulted in greater arousal, more frequent orgasms, and greater sexual satisfaction compared with placebo. Like for men, bupropion may be useful for sexual dysfunction in women. One small study ($n = 20$) found that women had significant improvement relative to placebo in all aspects of sexual function, including intensity of orgasm on either bupropion-SR 150 mg or 300 mg daily. It is important to note that several small-scale studies have assessed the effects of the above-mentioned drugs. The results are conflicting, and the drugs are not devoid of adverse effects. Currently, ongoing Phase I and II clinical trials for drugs to treat female sexual dysfunction include topical alprostadil, bremelanotide (BMT), intranasal testosterone (TBS-2), intravaginal dehydroepiandrosterone (DHEA), sublingual testosterone with sildenafil, apomorphine, bupropion, and trazodone.

Illnesses Associated with Sexual Dysfunction

The treatment of sexual dysfunction can also be viewed through the lens of specific illnesses. Almost any illness may cause sexual dysfunction. Some of these illnesses may be gender specific, for example, “senile” vaginitis and prostate cancer, and others may impact both genders. Those most often associated with sexual dysfunction are illnesses that negatively impact physical stamina or cause pain, those that require medications that adversely impact sexual function, or those that impact the endocrine system, the reproductive system, or the nervous system. Table 55.6f–4 lists some of the illnesses which may cause sexual dysfunction in later life. Given that the prevalence of serious medical illness increases with age, it is not surprising that sexual dysfunctions are more common in older patients.

Table 55.6f–4.

Some of the Medical and Psychiatric Conditions Associated With Sexual Dysfunction in Later Life

Diseases That Negatively Impact Physical Stamina or Cause Pain

- AIDS
- Chronic fatigue
- Chronic obstructive pulmonary disease
- Congestive heart failure
- Coronary artery disease
- Degenerative joint disease
- Fibromyalgia
- Irritable Bowel syndrome
- Peripheral vascular disease
- Renal failure

Diseases That Require Medications That Adversely Impact Sexual Function

- Cancer
- Hypertension

Disease of the Endocrine System

- Diabetes mellitus
- Hypercortisolism (Cushing syndrome)
- Hyperpituitarism (Acromegaly)
- Hypopituitarism
- Hyperthyroidism
- Hypothyroidism

Reproductive System Diseases

- Breast cancer
- Cervical cancer
- Ovarian cancer
- Prostate cancer
- Testicular cancer
- Uterine cancer

Diseases of the Nervous System

- Alzheimer dementia
- Epilepsy
- Generalized anxiety disorder
- Major Depressive disorder
- Multiple sclerosis
- Obsessive-compulsive disorder
- Panic disorder
- Parkinson disease
- Schizophrenia

In a patient with chronic renal disease, sexual function may be diminished due to fatigue and malaise. Chronic renal disease may also lead to sexual dysfunction due to associated vascular disease, neuropathies, and endocrine abnormalities. For example, both free and total testosterone levels are lowered in chronic renal disease but may return to normal following transplantation. In patients with chronic renal disease, sexual dysfunction may also be related to abnormalities between the pituitary and the Leydig axis. Both vitamin E and erythropoietin have been reported to improve sexual function in men with renal failure.

Studies have found that cardiovascular disease, including myocardial infarction (MI), may physically and psychologically interfere with sexual functioning and negatively impact all three phases of the sexual response cycle in older women as well as older men. Following an MI, many patients have concerns about intercourse that include anxiety about the inability to perform or fear that one may die during coitus. Angina may contribute to fears of having an MI during sex and reduce libido. In addition, the anxiety and depressive disorders that commonly occur after an MI may themselves cause sexual dysfunction.

Sexual intercourse places roughly the same demands on the heart as a vigorous walk around a city block. There is great intersubject variability in blood pressure and heart rate increases during sexual intercourse. Generally, an individual who can walk vigorously or pedal 600 kpm per minute on a stationary bicycle without symptoms, increased blood pressure, or electrocardiogram changes can safely engage in sexual intimacy, including coitus. Sexual abstinence is recommended for 8 to 12 weeks after MI, although there is minimal evidence to justify this in uncomplicated patients. After this period of abstinence, gradual resumption of sexual activity is recommended, often beginning with sexual experiences other than sexual intercourse. Because superior positions may heighten cardiac demand, side-by-side or patient-inferior positions may be recommended when coitus is initially resumed. In selected patients, the use of beta blockers and sublingual nitrates prior to intercourse may reduce angina. Patients who benefit from the use of nitrates must be instructed not to use phosphodiesterase inhibitors.

Chronic pulmonary disease impacts sexual function in at least two ways: chronic arterial hypoxia is believed to cause testosterone reductions and associated diminished desire in both men and women, and shortness of breath may limit physical ability to engage in sexual activity.

Both insulin-dependent (Type I) and noninsulin-dependent (Type II) diabetes mellitus (DM) may contribute to sexual dysfunction in men and in women. ED has been reported in up to 50% of men with Type I DM and in up to 33% of men with Type II DM. As men living with DM age, the rate of ED may approach 70%, and comorbid smoking and alcohol abuse predict earlier onset of ED. Men living with DM are believed to develop ED secondary to neurologic or microvascular lesions, and, as a result, the presence of any of the “opathies” will be associated with ED. Sexual dysfunction in women with DM is often overlooked but may occur at a rate as high as 50%. Dyspareunia secondary to decreased vaginal lubrication and difficulty achieving orgasm are among the problems reported by women living with DM.

A patient living with cancer may experience sexual dysfunction due to psychological factors, physical problems directly related to cancer, including pain, and side effects of the treatments. Women diagnosed with breast cancer may experience grieving and fears of death and disfigurement that decrease libido even before any treatment has been provided. Women whose treatment includes mastectomy and who have a history of marital difficulties, and who do not discuss with their spouse the possibility of mastectomy are at increased risk for sexual problems. A recent study compared women who had a lumpectomy to women who had a mastectomy and found that having a lumpectomy was associated with a greater sense of sexual desirability but no difference in the frequency of sexual experiences or orgasms. The treatment of sexual dysfunction following mastectomy includes minimizing medical problems that are inhibiting sexuality. Medical issues that contribute to sexual dysfunction in women undergoing treatment for breast cancer include dyspareunia and other forms of pain, fatigue, ovarian dysfunction from chemotherapeutic agents such as tamoxifen, and nausea and vomiting associated with chemotherapy. If possible, open communication between the patient and her sexual partner is helpful during all stages of treatment. It is helpful for the partner to observe the mastectomy wound soon after surgery. Rapid resumption of sexual activities is also believed to be helpful, and alternative sexual positions and vaginal lubrication may be helpful. Lastly, breast reconstruction may help improve self-image and restore self-esteem, both of which may contribute to improving sexual functioning.

Although testicular cancer is relatively uncommon in older men (incidence is highest at about 35 years of age, then declines to nearly zero by the age of 80), staging surgery may result in ejaculatory dysfunction and ED. Even in the absence of these problems, surgical removal of one or both testicles may cause problems with self-esteem. However, the increasing use of testicular prostheses has greatly reduced this concern for most men. Prostate cancer increases in frequency with age. The relative success of nonsurgical interventions and the introduction of surgical techniques, which are nerve-sparing, have helped to decrease ED and other sexual problems in men being treated for prostate cancer. Patients may need to wait 2 to 3 years following surgery for maximum sexual function to return. One study reported that radiation therapy caused ED in over 50% of the men who were studied.

As is true for male genital malignancies and for breast cancer in women, female genitourinary cancers are often associated with serious emotional problems which impact sexual function. Sexual difficulties with cervical carcinoma vary with the treatment approach. In general, surgery has fewer side effects than radiation therapy. Radical hysterectomy compromises sexual function because of vaginal shortening, but this may improve when there is ongoing sexual activity. The most important variable predicting sexual dysfunction following hysterectomy is whether the ovaries are removed. Radiation therapy promotes vaginal atrophy and stenosis due to impaired ovarian function. The extent of surgical treatment for vulvar carcinoma often determines sexual side effects. From a medical perspective, local excision often does not interfere with sexuality. More extensive surgeries may cause numbness.

Sexual problems in patients diagnosed with colon cancer are usually related to chemotherapy-associated side effects or to surgeries resulting in ostomies. Fear of fecal spillage and odor may inhibit sexual enjoyment. Women with ostomies can develop dyspareunia due to fistula formation. Men who require posterior abdominal perineal resection may become impotent due to the ablation of autonomic nerves to the penis.

The desire or need to express one’s sexuality does not expire with age, and for many older people, including those living in an aged care facility, sexuality continues to be important. A variety of outcomes have been observed when a spouse or significant other has dementia. Research indicates that 73% to 80% of the time, the presence of dementia has a negative impact on a couple’s sex life. Conversely, about one-quarter of the couples who have been studied continue a warm and satisfying sexual relationship. A significant number of sexually inactive caregiving partners (39% in one study) are dissatisfied with the inactivity. Clearly, there is no one right answer for everyone. Ballard and Poer have written that in the absence of a cure or treatment, the most significant thing that can be done for a patient with dementia is to adapt our approaches with each change in symptoms to make life as meaningful and satisfying as possible. Though written with the patient in mind, this quote and underlying sentiment seem equally relevant to caregiving spouses or partners. For patients with dementia and/or their caregiving partners, the opportunity to discuss their sexual concerns with a health care professional can be tremendously helpful. According to research, however, health care professionals only rarely inquire about the impact that dementia is having on a couple's sex life.

Among the factors that may influence whether a couple continues to have satisfying sexual experiences are:

1. the type of dementia
2. the stage of the dementia
3. the couple's previously established patterns of sexual intimacy
4. the impact of dementia on the patient's ability to maintain two-sided intimacy
5. the impact of dementia on the patient's knowledge of how to engage in and follow through with various sexual activities and on the sexual activities may be preferred or even demanded
6. the influence of dementia on the patient's personality, libido, grooming, and personal hygiene
7. the impact of dementia on the caregiving partner's view of the patient
8. the effect of caregiving on the spouse or sexual partner of the patient
9. whether the patient with dementia is able to continue living at home or requires institutionalization

Regarding the partner with dementia, possible changes include remaining interested but developing problems with follow through or with apraxia for one or more sexual acts, becoming hypersexual, or making new or unusual requests regarding sexual activities. At the time of diagnosis, ED may be present in around half of the men living with dementia. At some point, the erosion in intellectual function may make it difficult or impossible to accurately assess the sexual health of the relationship and to provide emotional intimacy.

For a variety of reasons, a caregiving spouse or partner may lose interest in sex. This loss of interest may be the result of overwhelming grief or physical exhaustion from the demands of caregiving. Sometimes caregiving partners deny their own needs, including their sexual needs to assuage survivor guilt or as a way of showing their respect for and loyalty to the person with dementia. It is also possible that dementia may cause such drastic changes in the patient's values and personality that the caregiving partner sees the patient as a child or in other ways so different that sexual intimacy begins to feel wrong or uncomfortable. Caregiving partners may sometimes need to be reminded that they do not have to participate in an activity that is frightening, upsetting, or no longer satisfying. A caregiving partner has the right not to be abused. Due to the level of the patient's cognitive impairment, the caregiving spouse may wonder if having sex with the partner is a form of rape. Ballard and Poer suggest that if the dementia patient initiates the experience and if the experience is mutually satisfying to both, then it should not be viewed as rape. It is quite possible that a patient might be incapable of giving informed consent for medication or research because of the complexity and novelty of the decision but still might be capable of giving informed consent to participate in a sexual relationship, a decision that is based more on old learning.

Patients with Alzheimer dementia will usually experience dramatic changes in short-term memory relatively early in the course of the illness. But personality and social graces do not erode until relatively late in the illness. The preservation of personality and social skills may allow a couple living with Alzheimer dementia to maintain satisfying sexual experiences through most of the illness as long as ED is not problematic. One of the earliest studies of sexual function in patients with Alzheimer dementia found that loss of erection was reported in 53% of male patients around the time of their initial diagnosis. In addition to ED, another potential situation that may negatively impact the quality of sexual life of a couple living with dementia is when short-term memory deficits trigger delusions of infidelity because the patient with dementia has trouble remembering where the caregiving spouse has gone or how long the partner has been absent and then begins to suspect that the partner is having an affair.

Patients with frontotemporal dementia (FTD) very often experience personality changes or profound language problems early in the course of their dementia, and either of these can negatively impact the sexual quality of life. For example, personality changes may cause the patient with dementia to behave so differently that their partner begins to feel as if they are with a stranger. Sometimes the expressive or receptive aphasia seen in patients with FTD is so severe that it is no longer possible to maintain two-sided intimacy that, for some patients and their partners, is an essential ingredient for safe and satisfying sexual experiences.

The later the stage of the dementia illness, the more difficult it becomes to maintain sexual intimacy. One study of 20 Caucasian male Alzheimer patients and their nondemented caregiving wives found that the patients with dementia reported no reduction in quality of sexual function regardless of the stage of illness. The wives of these patients, however, reported that the more advanced the stage of dementia, the worse their quality of sexual life became. The life expectancy of patients with many forms of dementia may exceed 12 years or more. For some healthy, active spouses, this may become an unacceptably long time to live without satisfying emotional and sexual experiences. Certainly, giving and receiving affection, and physical intimacy, are needs that do not die with the overwhelming responsibilities of becoming a caregiver. As a result, some caregiving spouses may begin a new intimate relationship while continuing to provide for the needs of the ill partner. When this occurs, the adult relatives of the patient with dementia may have a variety of reactions. Some family members may be very sympathetic. Others may fail to understand the healthy partner's need for an intimate relationship. Other family members may feel the need to protect the ill partner's interests or may have fears that the well partner's new alliance will threaten the financial assets of the ill partner or of their own anticipated inheritance. Sometimes the most difficult aspect of the well partner's decision to begin a new intimate relationship is that this decision makes it impossible for other family members to deny the reality of the tragic illness that has befallen the patient with dementia.

Dementia may also include the development of inappropriate sexual behaviors and the development of behaviors that appear sexual but are actually not. Caregivers of patients with dementia, whether a partner, some other family member, or a paid professional, may experience distress, discomfort, and uncertainty about how to manage inappropriate sexual behaviors. Professionals should assess these behaviors with the assumption that there is a valid need to be met, keeping in mind that not all behaviors that appear sexual may be sexual. For example, touching the genital area repeatedly may not represent masturbatory efforts but may be a signal that help with toileting is needed. Climbing in bed with the patient in the room next door may not be an act of sexual aggression but the expression of a desire for comfort, companionship, or protection or simply the expression of a lifelong habit of having a bed partner. The long-term care section of this chapter contains further discussion of this topic.

Medications Associated With Sexual Dysfunction

A variety of classes of medications and specific individual medications may cause sexual dysfunction in adults of all ages, including older adults. Table 55.6f–5 provides a list of some of the medications which have the potential to cause sexual side effects. Several classes of psychotropic medications can negatively impact sexual function. Men may experience ED from SSRIs. Both men and women may experience decreased sensitivity of the genitalia, delayed orgasm, or anorgasmia from SSRIs. Any of the psychotropic medications with significant dopamine receptor blocking ability may also cause a variety of sexual problems, which are believed to be mediated, at least in part, through medication-associated hyperprolactinemia and associated decreased androgen levels. Drugs, which increase gamma amino butyric acid (GABA) activity, such as benzodiazepine, have been reported to cause less satisfying orgasms for women.

Table 55.6f–5.

Some of the Medications Associated With Sexual Dysfunction in Later Life

Analgesics

- Methadone
- Morphine sulfate

Anti-Infective Medications

- Ketoconazole

Antineoplastic Medications

- Tamoxifen

Cardiovascular Medications

- Amiodarone (Cordarone)
- Angiotensin-converting enzyme inhibitors
- Calcium channel blockers
- Clonidine (Catapres)
- Digoxin (Lanoxin)
- Disopyramide (Norpace)
- Guanethidine (Ismelin)
- Prazosin (Minipress)
- Reserpine
- Spironolactone
- Thiazide diuretics

Endocrine Medications

- Adrenal corticosteroids
- Leuprolide (Eligard, Lupron)

Gastrointestinal Medications

- Cimetidine (Tagamet)

Neurologic and Psychiatric Medications

- Antipsychotic medications
- Benzodiazepines
- Carbamazepine (Carbatrol, Equetro, Tegretol)
- Carbidopa/levodopa (Sinemet)
- Divalproex sodium (Depakote)
- Lithium carbonate (Eskalith, Lithobid)
- Monoamine oxidase inhibitors
- Phenytoin (Dilantin)
- Primidone (Mysoline)
- Selective serotonin reuptake inhibitors
- Trazodone
- Tricyclic antidepressants
- Venlafaxine (Effexor)

Other

Diphenhydramine (Benadryl)
Cocaine
Hydroxyzine (Atarax, Vistaril)
Nicotine
Alcohol

Antihypertensive medications may also impair sexual function, although recent research suggests that beta-adrenergic blockers may not be as problematic as originally believed. Digoxin may decrease sexual desire. Agents which block the histamine receptor subtype 2 (H2 blockers) frequently interfere with penile erections, although not all medications in the class may do this equivalently. For example, cimetidine is more likely than ranitidine to cause ED. Lastly, alcohol, though not a medication, may seriously impair sexual function.

SEXUAL BEHAVIOR IN LONG-TERM CARE

In the United States, 4.2% of individuals 65 years old and older live in nursing homes (NH). This estimate does not include older adults living in other residential care settings. Over the past several decades, a spectrum of terms have been coined to describe the various levels of care provided by, and the configurations of, these residential care facilities for older adults, including independent living, assisted living, subacute care hospitals, rehabilitative facilities, and retirement communities. In addition to these terms, other terms describing housing options for older adults include senior community, 55 and up community, senior retirement community, senior living community, multilevel senior community, and continuing care retirement community (CCRC). In this manuscript, the abbreviation PRC (defined earlier in this manuscript) has been used when referring to the above spectrum of housing options for older adults. If something is unique to a specific housing option, this has been highlighted. As the older adult population increases, our understanding of each PRC setting's unique cultural environment will be critical to implementing successful transitions and promoting the health and well-being of older adult residents.

The exact numbers of older adults living in each type of senior housing across the United States are not available due to the heterogeneity of labels and defining features, as well as the lack of central data collection. In 2017, the not-for-profit senior living organization National Senior Campuses reported over 19,000 senior living units across the United States, up from the

15,500 estimates provided in 1998 by The American Senior Housing Association (ASHA), currently estimates that one million Americans live in some type of senior living community and that number is expected to double by the year 2030.

Most older adults, even those residing in long-term care environments, maintain some level of sexual interest, albeit at decreased levels. Future cohorts of older adults are expected to have even greater sustained interest in sex, as well as a higher frequency of participation in sexual acts, as generational acceptance and the perception that sexuality is normal for older individuals increases. Evidence suggests, however, that sexual desire is mediated not only by age but also by psychosocial factors, including partner availability, frequency of contact, and generational perceptions of the appropriateness of sexual activity in later life, as well as biologic factors, including the presence of chronic diseases and the medications used to treat them. For residents living in long-term care settings such as assisted living, one or more of these factors are likely to be highly relevant. A survey of 250 NH residents in Texas determined that only 8% of them had been sexually active (masturbation or intercourse) during the previous month, but 17% of the inactive residents said they would have liked to be active but lacked the opportunity. Preferred forms of sexual expression vary widely. Sexuality and intimacy are manifested in various ways, including intercourse, but findings overwhelmingly reveal that intimate touch, hand holding, and other less physically intense expressions are common and valued, just as significantly as younger individuals might enjoy more vigorous physical expressions of sexuality.

Although addressing the continuing sexual needs of older residents of PRC settings can be a difficult task to accomplish, these should be addressed with the same priority as nutrition, hydration, personal hygiene, and other well-accepted needs. Older members of gender and sexual minorities are especially at risk for challenges and difficulties with comfortably meeting their sexual needs in a residential care environment. Sexual behavior in PRC facilities is no longer a private matter and is often open to public scrutiny. In one way or another, sexual behavior in PRC facilities has an impact on staff members, other residents, and the families of residents and is, therefore, much more often inhibited by other residents, staff, and family.

The biggest potential barriers to achieving sexual satisfaction for residents are:

1. the culture of the residential care community, including the discomfort nurses, physicians, and other health care providers may have in discussing sexuality with older adults
2. the physical design of the PRC environment
3. existing government policies and regulations
4. internalized ageism, heterosexism, homophobia, and transphobia among the residents
5. attitudes and preferences of family members

Historically, the culture of most residential care environments for older adults has not supported the sexual needs of their residents. Although there is an increasing emphasis on the application of person-centered approaches to care delivery, many providers of residential care services for seniors still neglect to recognize and address sexuality as a component of well-being. The cultural beliefs and attitudes of personal and professional caregivers are major contributors to the culture of the PRC community and may become another common obstacle to sexual expression. Many administrators and caregivers are unaware of the importance of facets of the care environment that impact the ability of residents to express their sexuality and are unaware of what sort of support may be required. Studies have shown that NH staff members' attitudes about later-life sexuality are primarily negative. Such attitudes often lead caregivers and members of the management team to view any attempt at sexual expression as inappropriate, even by residents without cognitive impairment.

The policies of PRC facilities regarding sexuality are sometimes informal and vague. For example, some assisted living directors instruct their staff to leave quietly when they observe sexual activity in residents' apartments. The responses of PRC community administrators and staff members to sex and intimacy among residents are context related. Directors and staff members rely on the wishes and directives of the family members and powers of attorney. Directors can be permissive if the family is supportive of the sexual relationship but can reinforce limit setting if the family is not accepting the behaviors. If an assisted living setting has a low census of patients, policies may become more flexible: Problematic sexual behavior may be discouraged, but impulsive patients will not be banned. Advance directives are generally used to give guidance concerning medical care, not sexual relationships. As directives become more widely used, however, they may also be used to specify other aspects of care the patient wishes to receive when incompetent, including sexual behavior. In fact, some individuals may feel so strongly about loyalty to a spouse or religious belief that they may include directives concerning future sexual relationships. Cultural training around the healthy expression of sexual behaviors in older adults may be needed to ensure that older adults who want to remain sexually active receive proper acceptance, education, understanding, and support, even after moving to a residential care community. Another barrier to satisfying sexual experiences for long-term care residents is the lack of knowledge and understanding among the residents themselves about later-life sexuality, and so residents may also benefit from education about later life sexuality. Physical aspects of life in a residential care environment are another common and significant barrier to sexual intimacy, such as living in a shared room with only a curtain between the beds for privacy.

Government policies and regulations also have a large impact on the culture of PRC communities. Eighteen states in the United States address the issue of married couples sharing rooms or having conjugal visits unless there is any medical contradiction (Federal regulation 483.10). Only four states allow room for sexual relationships between persons of the same gender, as well as persons of the opposite gender who are not married. Such recognition seems to be important to assure that NH residents have the same rights as other citizens in this regard.

Despite the difficulties associated with methods and measurement, evidence to date suggests that quality of life in residential care environments for older adults is largely determined by the presence of mental health problems and one's subjective sense of well-being. Research also suggests that both the individual's cultural identity, the sensitivity of the treating team towards this identity, and the culture of the residential care environment can significantly impact the mental health and perceived quality of life of older adults living in a residential care home. As a result, mental health care providers play an integral part in the care of older adults residing in NHS and other PRC environments.

LGBTQ+ Individuals and Long-Term Care

According to the National Gay and Lesbian Task Force, there are currently between 1.4 and 3.8 million lesbian, gay, bisexual, and transgender (LGBT) Americans over the age of 65. They remain particularly at risk of both homophobia, transphobia, and heterosexism, especially those who are residents of PRC facilities. Homophobia is defined as the unreasonable hatred, prejudice, and fear of LGB people. Transphobia is the term to describe hatred, prejudice, and fear of transgender individuals. Heterosexism and cisgender status function as default assumptions; it is a bias where the heterosexuality and cisgender of most people are presumed. Institutional heterosexism relies on the assumption of heterosexuality as the norm and results in the health needs of LGBT people being neglected. Since the U.S. Supreme Court legalized same-sex marriage in all fifty states, federal recognition of same-sex unions has allowed them to receive the financial and other benefits that come with opposite-sex marriages. As LGBT people age and become more dependent on federal benefits, such as Social Security, Medicare, and Medicaid (none of which were previously extended to same-sex partners), and become more enmeshed in health care systems that do not grant their partners the same rights as legal spouses, they experience the effects of a lifetime of inequality. These effects can follow a lesbian or gay person into the NH or other PRC setting. In fact, “invisible” is a recurring description of older LGBTQ+ individuals. Although “passing” is used as a survival tactic to protect against discrimination, the trauma for those who have lived their lives openly and honestly but find themselves going back into hiding when “they become ill, vulnerable and dependent on others” should not be minimized. Transgender persons are at particular risk of avoiding institutions and situations where they would be forced to rely on assistance from insensitive and transphobic providers, for example, in vulnerable situations such as bathing.

Many LGBT older adults are concerned about entering NHs due to fears that they will be forced into the closet to avoid being shunned by other NH residents for being openly lesbian, gay, bisexual, or transgender. Others fear mistreatment by administrative staff, care staff, and peers. Furthermore, for a long time, most retirement communities in the United States were faith-based; this meant they could discriminate without bounds because of their exemption from most nondiscrimination statutes. As an alternative to faith-based homes, several retirement communities catering to the LGBT community have now opened around the country. The most well-known of these is called RainbowVision, the first U.S. retirement village designed specifically for gay men and lesbians in Santa Fe, New Mexico. Similar communities now exist in several major American cities.

Scientific evidence regarding the clinical preparedness for dementia care providers to care optimally for members of the LGBTQ+ community remains scarce. A nationally representative mail-in survey of NH social service directors, however, revealed that LGBT cultural training is still not the norm. More than 75% of responders reported not receiving any training during the previous 5 years. Recent work by Nowaskie and Sewell (2020) found that dementia care providers endorse only moderate clinical preparedness and knowledge about LGBTQ+ health care, especially with transgender-specific care. However, they do endorse strong positive attitudes about the LGBTQ+

population, which may facilitate the recognition of the need for improved education and training. The current state of dementia care providers' LGBTQ+ cultural humility has, nonetheless, significant yet modifiable gaps. For those engaged as dementia caregivers, better education and more LGBTQ+ patient exposure (e.g., through patient panels and cultural humility training) are necessary in order to improve the care being provided to members of the LGBT community impacted by dementia illness. The LGBT Cultural Competency Project is an example of a collaborative initiative between multiple partnerships with a primary goal of providing education and awareness of the unique needs and concerns of LGBT older adults who are aging into long-term care communities. Some NHs, including those that do not specifically cater to the LGBT community, have endorsed the HEALE curriculum. The HEALE curriculum sets a standard for best practices in nursing management and for LGBT cultural competency in geriatric education. The nurses' HEALE training has significantly increased knowledge and, as a result, nurses' confidence in providing culturally sensitive care to older LGBT individuals. In 2015, OutCare was established as the nation's first comprehensive resource for LGBTQ+ health care. The support provided by OutCare includes provider and health care resource directories, including an online, nationwide directory of health care providers who identify as culturally competent in the care of the LGBTQ+ community, mentorship, and cultural competency training.

Lastly, family members may also be a barrier to sexual satisfaction for older adults living in a long-term care environment. Family members may have difficulty understanding and accepting that their older relative is having a sexual relationship with someone new. Sometimes their concerns may be legitimate (e.g., worry about STDs), and sometimes their concerns may have the appearance of being self-serving (e.g., concerns about the relationship's potential impact on inheritance).

Cognitive Capacity for Decisions Regarding Sexual Behaviors

Determining whether two patients, both of whom have dementia, should be allowed to share sexual intimacy may provoke feelings of anxiety or discomfort, but this has and will continue to be required of health care professionals. There are no universally accepted criteria or processes for determining the capacity to consent to sexual experiences. The assessment process should be initiated when there is evidence that the presence of a mental health or neurocognitive condition is impairing decision-making abilities, undertaken according to legal standards, and with the burden of proof on those alleging incapacity. In addition, upholding the basic human right of autonomy requires that cognitive capacity be viewed as specific to a situation or decision. Individuals who have legally established guardians or another form of proxy decision maker may still retain the capacity to consent to engage in intimate relationships.

Lichtenberg and Strzepek have published the only formal capacity assessment tool in this area, a semistructured interview tool based on the principles of informed consent. The tool requires that older adults have a basic level of cognitive functioning, and they chose a score of 14 or greater on the Mini-Mental State Examination (MMSE) as confirmation. Subsequently, an interviewer of the same sex as the older adults must assess each patient according to three criteria each patient's awareness of the relationship (e.g., Is the patient aware of who is initiating the sexual contact or is the person being misidentified as someone else such as a deceased spouse?); the potential risks (Can the patient describe how they will react if the relationship ends?); and the ability to avoid exploitation (Does the patient have the ability to state what level of sexual intimacy is desired and to say no to any uninvited or unwanted sexual act?). The results of both interviews are then reviewed by the members of the interprofessional team, and members vote to determine if the criteria have been met.

The Vancouver Coastal Health Authority (VCHA) recently created guidelines to assess intimate relationship decision making when one or both older adults may lack cognitive capacity. These guidelines are based on the premise that PRCs have an ethical and legal obligation to recognize, respect, and support the sexual lives of their residents and were created as a guide for PRCs to determine how best to achieve this obligation while also supporting staff and care providers. If an older adult is found to lack capacity, then a team that includes a family member should assemble to decide whether the intimate relationship will be permitted.

The three key recommendations from the VCHA guidelines are:

1. If a person has been appointed by the court or the client to make decisions specifically about sexual activity, then that person is the resident's decision maker regarding intimacy;
2. If no one with legal authority has been appointed by the court or the client to make decisions specifically about sexual experiences, then a group including a family member, assessing clinician, and PRC community representative should convene to determine whether sexual activity is in the best interest of the resident; and
3. The resident should be included in the decision-making process to the fullest extent possible.

Additional helpful guidance is available from The Hebrew Home at Riverdale in Riverdale, New York, which has posted online a copyright-protected document titled: “Policies and Procedures Concerning Sexual Expression at the Hebrew Home At Riverdale.” The intent of this document is to create a culture that recognizes and respects the importance of emotional intimacy in the lives of older adults. Such close human interactions are viewed as a normal and natural aspect of daily life.

The Hebrew Home at Riverdale policies specify that residents have the right to sexual activity, providing in each instance that the activity does not involve:

1. nonconsensual acts;
2. acts with minors;
3. acts between persons if there is a possibility of transmission of an STD; and
4. acts that impact negatively on the resident community as a whole through public display.

The guidelines for assessing consent to sexual activity contained in this document are available at the Hebrew Home’s website: www.hebrewhome.org.

Recommendations for PRC Communities

A federal appeals court recently upheld a finding by the CMS Appeals Board that NHs have an obligation to intervene when residents with dementia or Alzheimer disease engage in sexual activity and that the level J violation and the immediate jeopardy findings against the NH were correct.

The appeals court ruled that the NH had failed to properly intervene when three residents living with dementia engaged in sexual intimacy because the facility failed to;

1. talk to the residents about their feelings regarding these relationships,
2. document the residents’ capacity for consent, and
3. obtain medical assessments of how the residents’ cognitive deficits affected their capacity to consent.

In order to provide the highest quality experience possible for residents while also protecting the PRC community from allegations of medicolegal or ethical misconduct, it is important for every PRC to create written and readily accessible policies to ensure that a resident’s right to safe and healthy sexual expression is recognized, respected, supported and maintained while ensuring that the ability of residents living with cognitive problems has been properly confirmed and documented. Optimally created policies should include the requirement for ongoing and recurring staff training and case discussions. In addition, sexuality, including gender, preferred pronouns, sexual orientation, relationship status, and sexual needs, desires, and concerns, should be routinely assessed during the resident's initial visit with the community's nurse or physician and no less than annually thereafter. The community should create and maintain an atmosphere where the privacy of residents is respected. Staff should be required to document any relationship or intimacy concerns, including any proposed corrective actions.

The topic of sexual behavior in older adults often reveals ageistic beliefs and may sometimes illicit polarized viewpoints among patients, their family members and friends, and those who care for them. It is recommended that family members be informed of the community's policies regarding intimate relationships and sexual expressions. In the absence of capacity concerns, the resident's permission should be obtained for one or more family members to be included in any discussions surrounding resident intimacy issues. Like the need for staff training, the family members and friends of older adults may need education about the fact that, in spite of frailty or dementia, many older adults continue to have sexual needs that are unique and real.

Inappropriate sexual behavior among long-term care residents includes using sexually suggestive language, exposing oneself, masturbating, or openly participating in sexual activity with another resident. Whether in the long-term care environment or at home, the approach to sexually inappropriate behaviors is the same. If the problem sexual behaviors are new, a careful evaluation should take place. Underlying medical (e.g., bilateral medial temporal lobe injury), psychiatric (e.g., hypomania or mania), psychosocial (e.g., loneliness), and environmental (e.g., use of confusing terms of endearment by staff members such as "honey or "sweetheart") need to be investigated and addressed while concurrently implementing behavioral interventions. In order to avoid precipitating a "catastrophic reaction," it is important not to scold, argue or shame the person. Praising and encouraging acceptable behaviors and ignoring inappropriate behaviors may be helpful. Remaining calm helps to avoid rewarding unwanted behaviors. Sometimes inappropriate sexual behaviors may be triggered by underlying feelings of loneliness, isolation, or anxiety. Sometimes unmet sexual needs may trigger anxiety, frustration, or restlessness. Either way, providing appropriate forms of attention and physical affection proactively may prevent, reduce or eliminate problematic sexual behaviors.

Depending on the specific behavior, different solutions should be explored. For example, for the patient who repeatedly masturbates in public places, providing privacy as well as other things like a vibrator, personal lubricant, or condom may be helpful. If a patient disrobes in public, dressing the patient in clothing that makes disrobing difficult may help. For patients who expose themselves unnecessarily during personal care or become sexually aroused, it is important to set limits verbally, involve more than one caregiver, and, depending on the patient's sexual orientation, use caregivers whose gender is not the gender that stimulates the patient, and make the interactions as clinical as possible by wearing medical attire like a white coat and gloves, and performing these activities in an examination room rather than in the resident's room.

If treatment of all potential causes of inappropriate sexual behaviors coupled with behavioral interventions is unsuccessful, a medication trial may be needed. Table 55.6f–6 lists medications that may be helpful, including various forms of estrogen and SSRIs. Mood stabilizers may be useful even if hypersexuality is occurring in the context of a manic-like syndrome that does not fulfill all of the DSM 5 diagnostic criteria for mania. Antipsychotic medication may be helpful if the sexual behavior is driven by a delusion of mistaken identity in which the patient is attracted to a person misidentified as the patient's spouse or former sexual partner.

CASE EXAMPLE

The following case highlights a number of key issues associated with sexually inappropriate behaviors in patients living with dementia:

1. Although these behaviors can arise in patients living with a variety of types of dementia, they are most often seen in patients whose dementia has preferentially injured the frontal lobes resulting in problems with judgment and impulse modulation.
2. These behaviors are more likely to occur in later stages of dementia, resulting in sexually inappropriate behaviors occurring in the midst of other types of behavioral challenges.
3. Wide variation in both sex hormone levels and their impact on physical characteristics and behavior often limits their value in establishing the etiology of sexually inappropriate behaviors (this patient's measured serum testosterone level was actually low).
4. Medroxyprogesterone acetate (MPA) may help reduce but may not eliminate sexually inappropriate behaviors completely.

5. The use of MPA requires careful monitoring due to potential side effects that limit its usefulness and safety.

Table 55.6f–6

Medications for Hypersexuality in Patients With Dementia

Medication	Preparation	Suggested Dosage	Potential Side Effects
Hormonal Agents			
Antiandrogens			
Medroxyprogesterone acetate (Depo-Provera)	IM injection 150 mg/mL	150–300 mg once a week	Sedation, weight gain, fatigue, hot and cold flashes, depression
Estrogens			
(Premarin)	0.3-, 0.45-, 0.625-, 0.9-, 1.25-mg tablet	0.625–2.5 mg/day	Increased risk of cardiac death in men with prostate cancer, fluid retention, nausea, vomiting, gynecomastia
(Enjuvia)	0.3-, 0.45-, 0.625-, 1.25-mg tablets		
(Climera)	0.025-, 0.0375-, 0.05-, 0.06-, 0.075-, 0.10-mg/day transdermal patch	0.05–0.1 mg/day	
Gonadotrophin-releasing hormone analogs			
Leuprolide acetate (Eligard)	Injectable suspensions: 7.5-, 22.5-, 30-, 45-mg/month	7.5 mg every 4 weeks or every 8 weeks	Hot flashes, erectile dysfunction, irritation at injection site
(Lupron Depot)	3.75-, 7.5-mg/month		

	11.25 mg every 3 months		
Serotonergic Agents			
Serotonin reuptake inhibitors			
Citalopram	10 mg/5 mL oral solution, 10-, 20-, 40-mg tablets	20 mg/day	Headache, nausea, diarrhea, loss of appetite, insomnia
Paroxetine	10 mg/5 mL oral suspension 10-, 20-, 30-, 40-mg tablets 12.5-, 25-, 37.5-mg controlled-release tablets	20 mg daily	
Tricyclic antidepressants			
Clomipramine	25-, 50-, 75-mg tablets	150–200 mg/day	Orthostatic hypotension
Trazodone hydrochloride	50-, 100-, 150-, 300-mg tablets	100–500 mg/day	Sedation, hypotension, priapism
Antipsychotics			
Atypical antipsychotics			
Quetiapine	25-, 100-, 200-, 300-mg tablets	25 mg/day	Orthostasis, sedation, increased death due to cardiovascular events
Mood Stabilizers			
Carbamazepine	100-mg chewable	50–300 mg/day	Ataxia, dizziness, rash, sedation,

	tablet 200-mg tablet 100-, 200-, 400-mg extended-release tablets 100-, 200-, 300-mg capsule 100 mg/5 mL and 200 mg/10 mL suspensions		nausea, vomiting, hyponatremia, agranulocytosis, aplastic anemia, falls
Valproate	250-mg capsules 125-mg sprinkle capsule 250-, 500-mg extended-release tablets 250 mg/5 mL syrup 100 mg/mL injection	500–1,500 mg/day	Nausea, sedation, falls, tremor
Other Agents			
Pindolol	5-, 10-mg tablets	40 mg/day	Fatigue, hypotension
Cimetidine	200-, 300-, 400-, 800-mg tablets 300-mg/L oral solution	600–1,600 mg/day	Headaches, nausea, arthralgias, delirium

The primary care physician (PCP) of a 91-year-old widowed male, a retired engineer with vascular dementia residing in a dementia-specific residential unit, requested a geriatric psychiatry consultation to evaluate depression and inappropriate sexual behaviors. Because of the severity of the patient's cognitive deficits, most of the history was obtained from collateral sources.

Prior to the emergence of the patient's dementia symptoms, the patient had no psychiatric problems or psychiatric treatment of any kind. His cognitive deficits were first recognized several years prior to the time of the consultation request following a stroke which left the patient with residual ataxia and pseudobulbar affect. About 5 months after his stroke, behavioral symptoms, including wandering and elopement attempts, required the patient to move from an independent living apartment to a dementia-specific assisted living unit. Several months later, a geriatric psychiatry consultation was obtained after the patient slapped the hand of a male peer because this peer had touched the patient's food. Following this incident, the patient told a nurse, "if it happens again, I'll break his hand off." The consulting geriatric psychiatrist (CGP) found no undiagnosed medical factors that might have caused the problem behaviors and observed that the patient was struggling with frustration related to both a loss of control and problems with short-term memory. The CGP recommended discontinuation of quetiapine, given its questionable efficacy and unfavorable risk-benefit profile in patients living with dementia, and initiation of treatment with dextromethorphan/quinidine to target the patient's emotional lability and impulsive behaviors. In addition, the CGP suggested that, if needed, a trial of divalproex might also be reasonable.

Several months later, when sexually inappropriate behaviors emerged, the patient's PCP independently changed the patient's psychiatric medications to escitalopram 10 mg PO daily and divalproex delayed release 250 mg PO twice daily (which yielded a trough serum level of 30 mcg/dL) and encouraged the staff to use a variety of behavior-modifying techniques including avoidance of the use of ambiguous terms of endearment such as "honey" or "sweetie" and responding to inappropriate sexual behaviors with simple, firm verbal limit setting in order to avoid unintentionally reinforcing these behaviors with excessive positive (laughter) or negative (anger) affect. The patient, however, continued to have frequent and disruptive inappropriate sexual behaviors involving staff members, including verbalizing requests for sex, kissing and groping staff members, and masturbating in public.

The patient had no known past psychiatric history of hypomanic or manic episodes. The patient's medical problems included congestive heart failure, diabetes mellitus, type 2, hypothyroidism, benign prostatic hypertrophy, a history of sinus surgery, and a stroke 22 months previously. His medications were: acetaminophen 500 mg PO TID, bumetanide 0.5 mg PO BID, clopidogrel 75 mg PO daily, divalproex 250 mg PO BID, doxazosin mesylate 8 mg PO Q PM, escitalopram 10 mg PO QD, lansoprazole 30 mg PO QD, levothyroxine 100 mcg PO QD, metoprolol 12.5 mg PO BID, probiotic containing saccharomyces boulardii lyo 250 mg PO BID, sitagliptin 100 mg PO QD, and vitamin B12 1,000 mcg PO QD.

On examination, the patient's vital signs were within normal limits. The CGP examined the patient in the common area and observed that he was a casually dressed and groomed Caucasian man who was seated in a wheelchair and had no observed abnormal movements. He was distant, detached, and disinterested. He reported feeling "pretty normal," denied any current symptoms of depression or anxiety but was unable to describe his current medications other than saying that he was taking "a bunch" and that he was not aware of any side effects. His affect revealed frustration and irritability, his speech was normal, his process of thought was linear, and the content of his speech was noteworthy for concreteness, sarcastic responses to most questions, and the absence of clear answers to questions about suicidal ideation, homicidal ideation, delusions, or hallucinations. He was oriented to self and attentive but refused to cooperate with a standardized bedside cognitive screening test.

None of the patient's medications were felt likely to be triggering the patient's sexually inappropriate behaviors, and the results of a wide range of laboratory tests obtained by his PCP 1 week prior did not reveal a medical problem that would explain the patient's inappropriate sexual behaviors. These lab results included a random glucose of 123 mg/dL (high), creatinine 1.64 mg/dL (high), albumin 2.9 g/dL (low), total protein 5.3 g/dL (low), hemoglobin 8.6 g/dL (low), hematocrit 25.7% (low), TSH 3.09 µIU/dL, prolactin 14.3 µg/L, FSH 15.5 IU/L (high), LH 7.5 IU/L, progesterone 0.5 ng/mL, testosterone 187 ng/dL (low). After obtaining informed consent from the patient's family, a trial of medroxyprogesterone acetate (MPA) 150 mg IM Q monthly was initiated. No other changes in his medications were made in order to clearly assess the impact of the addition of MPA.

One month later, the CGP learned from staff members that the patient was no longer propositioning or attempting to kiss or grope members of the staff, although he was masturbating in his room occasionally. When interviewed, the patient reported feeling “in and out” and being “pushed around” by “people like you [the psychiatrist].” The CGP concluded that the patient was demonstrating a favorable response to the treatment with MPA and recommended continuation of MPA along with ongoing use of nonpharmacologic measures. Two months after initiation of treatment with MPA, the patient had not had any problematic sexual behaviors but had been spending most of the day sleeping, had become apathetic about meals, would eat if spoon-fed, and had lost 17 pounds over the preceding three months. When interviewed, the patient was oppositional and antagonistic, denied depression and anxiety but reported feeling angry due to “people like you.” When the CGP asked the patient to elaborate, he replied, “You had better get your ass out of here and never come back.”

Due to concerns about potential divalproex-associated nausea and weight loss, as well as the absence of any clear benefit, divalproex was discontinued, and a trial of mirtazapine 7.5 mg PO QHS was initiated to help with appetite stimulation. Three weeks after this visit, the patient was transferred from the dementia unit to a skilled nursing unit due to poor safety awareness associated with a number of falls. During his first week in the new location, he had two episodes of inappropriate sexual behavior: he grabbed a nursing assistant’s buttocks and asked her if she wanted to see his “banana,” and he was observed patting his groin in a hallway. The CGP examined the patient in a public area of the skilled nursing unit and observed that he was hostile, intermittently scratched himself, and patted his exposed abdomen. When asked about the recently concluded music-based activity, the patient replied, “I was there because they dragged me in there,” and he reported feelings of depression because “I have to put up with people like you.” No changes in the patient’s treatment were recommended.

When the patient was assessed approximately 4 months after the initiation of treatment with MPA, the CGP learned that no episodes of sexually appropriate behavior had occurred during the past month, but several episodes of verbal and physically aggressive behaviors had been observed, including smearing feces, resisting attempts to change his soiled clothing and attempting to spit and urinate on staff members. The patient informed the CGP that he saw a “spirit.” His blood glucose at the time of this interaction was determined to be 587 mg/dL. After consultation with the patient’s PCP, a decision was made to discontinue MPA due to concerns that the patient had developed delirium secondary to MPA-associated metabolic/endocrinologic dysregulation.

55.6g HIV and Aging

Laura M. Campbell, M.S., María Marquine, Ph.D., and Raeanne C. Moore, Ph.D.

Once considered a death sentence, HIV has been transformed into a chronic disease as a result of highly active antiretroviral therapy (ART). The life expectancy of adults living with HIV that are receiving ART is now approaching that of the general population, and today more than half of persons with HIV in the United States are over age 50, with aging trends projected to continue. This remarkable success has brought with it a new set of challenges. As people with HIV are becoming older, HIV has become a chronic disease with multiple interacting causes of morbidity and mortality, generating significant public health interest in understanding the multiple factors that can impact aging with HIV.

Recognizing the issues and needs of the increasing older population of persons with HIV, a White House Conference on HIV and Aging was held in 2010, and the issue of HIV and Aging was again spotlighted at the 2015 White House Conference on Aging. In addition, the Office of AIDS Research of the National Institutes of Health (NIH) commissioned a working group to develop an outline of the current state of knowledge and areas of critical need for research in HIV and Aging. The findings and recommendations of the working group are summarized in a published report. While much research is needed to better understand health outcomes in older persons with HIV, the American Academy of HIV Medicine, in collaboration with the AIDS Community Research Initiative of America, developed a series of guidelines for clinicians managing older patients with HIV.

EPIDEMIOLOGY

In 2018, one in six (17%) of new HIV diagnoses in the United States were among older adults, and this rate has remained stable in recent years. Similar to younger age groups, members of racial/ethnic minority groups are at increased risk of HIV, with rates of infection in 2018 being 39.2 for blacks/African Americans, 16.4 for Hispanics/Latinos, 13.3 for persons of multiple races, 11.3 for Native Hawaiians/Pacific Islanders, 7.7 for American Indians/Alaska Natives, 4.8 for whites, and 4.7 for Asians. Older males are also at increased risk as compared to older females, with men making up the majority of new HIV diagnoses among people over the age of 50. As shown in Figure 55.6g–1, the most common forms of transmission vary by sex.

Older persons in the United States are more likely to be diagnosed with HIV later in the course of the disease compared to younger persons, which can result in worse disease burden and prognoses. For example, in 2015, over 50% of those diagnosed with HIV aged 55 and over had HIV for over 4.5 years prior to diagnosis, which is the longest diagnosis delay for any age group. However, in persons over age 55 with HIV, 71% received some HIV care, 57% were retained in care, and 64% were virally suppressed in 2018, which is better than the overall estimates for persons with HIV (65%, 50%, and 56% respectively).

Deaths of persons with diagnosed HIV may or may not be related to HIV. Of the estimated 15,484 deaths among people living with HIV in the United States in 2018, 11,425 (72%) were among people aged 50 and older. From 2014 to 2018, the death rate of persons with HIV aged 50 to 54 (rate = 11.9 in 2018) and 55 to 59 (2018 rate = 12.7) decreased over time, and the death rate of those aged 60 to 64 remained stable (2018 rate = 11.9), whereas the rate of death for persons aged 65 (2018 rate = 6.7) and older increased.

PREVENTION

Persons over the age of 50 appear to have several of the same risk factors for HIV as younger persons (e.g., sexual intercourse without protection, sharing drug equipment), which can be exacerbated by issues unique to older adults. Many older adults are sexually active, yet they may not consider themselves at high risk for HIV, may have less knowledge about HIV, and ultimately may be less likely to engage in HIV prevention. For example, older persons who are no longer concerned about pregnancy may be less likely to use condoms and/or other HIV prevention tools (e.g., pre-exposure prophylaxis [PrEP]). Additionally, age-related thinning and dryness of the vaginal tissue may place older women at an increased risk of acquiring HIV.

While there is much left to understand regarding the reasons driving later HIV diagnoses among older persons, some of the key reasons may be that older persons are less likely than younger persons to discuss their sexual habits or drug use with their doctors and that they might mistake HIV symptoms for those of normal aging. In turn, health care providers may also be less likely to ask about these issues and to test older persons for HIV. It also appears that HIV stigma might be of particular concern for older persons with HIV and may prevent them from seeking care and disclosing their HIV status.

Given these prevention challenges, the Center for Disease Control and its partners are implementing a High Impact prevention approach which includes new funding through the *Ending the HIV Epidemic* initiative, with the goal of reducing the number of new infections by 90% by 2030. This program includes a number of initiatives aimed at providing support and technical assistance to health departments and community-based organizations for implementing prevention programs, raising awareness about HIV, supporting HIV testing and optimizing linkage to care, increasing the percentage of those with viral suppression, and increasing PrEP prescriptions for people who may benefit from PrEP.

NEUROCOGNITIVE OUTCOMES OF HIV AND AGING

HIV and aging are independently associated with central nervous system (CNS) dysfunction. The co-occurrence of HIV and older age appears to have additive or synergistic negative effects on the CNS, with several studies observing elevated rates of neurocognitive impairment (NCI) and/or HIV-Associated Neurocognitive Disorders (HAND; see next paragraph) in older cohorts of persons with HIV. For example, in a meta-analysis from 2021 of 21 cross-sectional studies primarily from high-income countries, persons with HIV aged 50 and over were more likely to be cognitively impaired than HIV-negative controls (OR = 2.6). This meta-analysis found that older persons with HIV had lower scores in the domains of executive functioning, processing speed, verbal fluency, memory, and motor as compared to older HIV-negative adults. Several studies have also examined the issue of whether the combined effects of HIV and aging on NCI are evidence of premature (i.e., worse cognitive performance compared to HIV-negative peers), accentuated (i.e., higher rates of NCI compared to HIV-negative peers), or accelerated (i.e., a steeper decline in cognition compared to HIV-negative peers) aging. While the topic does remain controversial, a systematic review from 2020 of 37 studies found evidence for premature and accelerated but not accentuated aging.

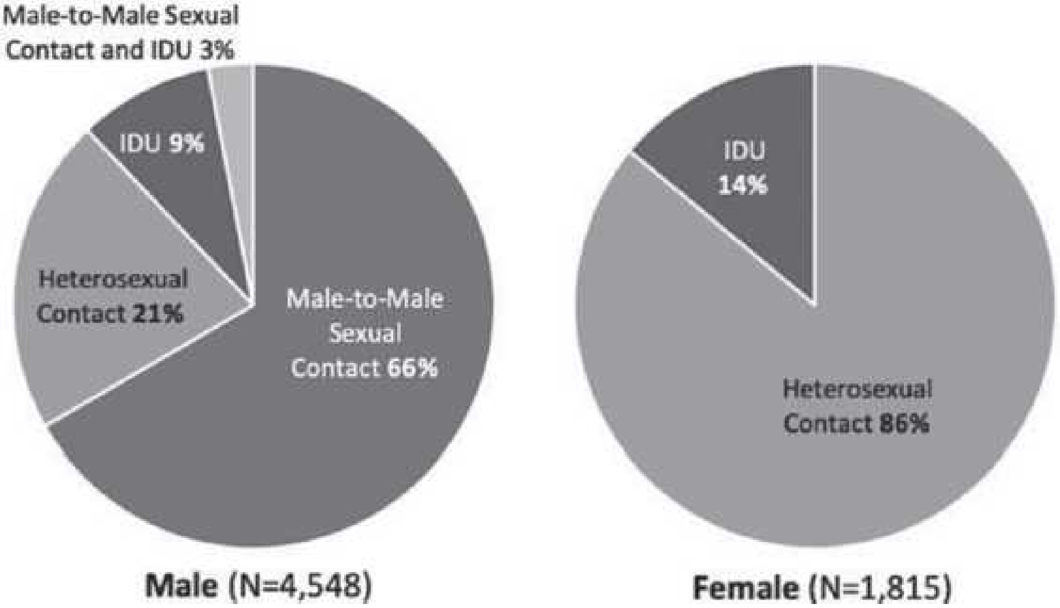

FIGURE 55.6g–1. New HIV diagnoses among adults aged 50 and older in the United States by sex* and transmission category in 2018. *Based on sex at birth and includes transgender people. IDU, injection drug use. *Due to rounding, percentages may not add up to 100%.* (From Center for Disease Control and Prevention: Diagnoses of HIV Infection in the United States and Dependent Areas, 2018 [Updated], 2020;31.)

Another factor to bear in mind for future studies in the area is that definitions of “neurocognitive impairment” can differ from study to study and often differ from the clinical definition of a “cognitive disorder.” For example, the Diagnostic and Statistical Manual of Mental Disorders-5th Edition (DSM-5) uses different criteria for defining a neurocognitive disorder than the current research criteria for HAND (i.e., Frascati criteria). For example, only problems on one neurocognitive domain are required by DSM-5 rather than two (per the Frascati criteria) to define impairment in “global” neurocognitive function implied by the term “cognitive disorder” (whether major or minor). Moreover, the exclusion criteria required for a diagnosis of neurocognitive disorder are limited to other psychiatric disorders per the DSM-5 but explicitly include CNS illnesses specific to the setting of immunodeficiency, as noted by both the original American Academy of Neurology (AAN) criteria and the current Frascati criteria. Moreover, different research criteria for cognitive impairment use different cut-points to define “impairment.” For example, Frascati criteria define impairment as performance at least 1 standard deviation below a demographically adjusted normative score in at least 2 domains, whereas some studies may employ stricter cut-offs. These differences in the research make it difficult to compare across studies and obscure the findings of future research.

While much is yet to be known regarding key predictors of NCI among older persons with HIV, a recent study investigated predictors of longitudinal neurocognitive decline in 436 adults with HIV (Age in years: Mean = 43.9, Standard Deviation = 8.4; Mean follow-up = 35 months). Results from multivariable models showed that key predictors of an earlier time to neurocognitive decline included Hispanic ethnicity, notable non-HIV comorbidity, being off ART, having low albumin and low hematocrit, having a lifetime methamphetamine use diagnosis, and increased depressive symptoms. These, along with other findings, suggest that a number of different factors (HIV and non-HIV specific) are probably important predictors of NCI in older persons with HIV.

As the population of persons with HIV continues to age, there is an increased need to understand the intersection of HIV and age-related neurodegenerative diseases such as Alzheimer’s disease. It is important to be able to differentiate between HAND and Alzheimer’s disease given the different prognoses: Alzheimer’s disease is associated with progressive cognitive and functional decline, whereas HAND is usually nonprogressive. Given that memory dysfunction is common in both HAND and Alzheimer’s disease, early signs of Alzheimer’s disease in persons with HIV may be missed or be attributed to HAND. This research is still underway, but it is an important topic of research that is necessary to be able to meet the health care needs of older persons with HIV.

MENTAL HEALTH OUTCOMES OF HIV AND AGING

Older persons living with HIV face unique emotional issues, including stigma, marginalization, and discrimination. In addition to emotional factors, these adults also often face unique social factors (e.g., lack of appropriate treatment facilities, poor access to health care, financial problems, disability) and unique family factors (e.g., HIV in a spouse, poor family support). These issues may make persons with HIV more vulnerable to psychiatric illness, decreased well-being, and poorer health-related quality of life. Depression is the most common psychiatric diagnosis among persons with HIV, with lifetime major depression disorder estimated between 25% and 45% among persons with HIV. However, despite depression being common in older persons with HIV, prevalence rates are not well studied, and depression is thought to be significantly underdiagnosed and undertreated in older persons with HIV. Additionally, the prevalence of other psychiatric conditions such as anxiety is thought to be increased in older persons with HIV as compared to HIV-negative peers, but again this is not well studied among older persons with HIV. Nevertheless, the cooccurrence of mental illness and HIV is associated with poorer health outcomes, such as increased rates of comorbid conditions and reductions in ART adherence. Efforts to integrate primary health care at Infectious Disease or General Medicine clinics with mental health treatment and to combat the societal stigma that is associated with mental illness and HIV are likely to improve the health and well-being of persons living and aging with this disease.

The role of mental health professionals in treating older persons living with HIV is threefold: (1) identify behavioral factors most saliently impacting the course of HIV and well-being outcomes to determine how and when to intervene; (2) work with the patient’s geriatrician and other primary care team members to determine the most appropriate course of treatment; and (3) implement treatment plan, closely monitor progress, and modify as needed.

Emotional Functioning

Depression management is a priority to achieve optimal health outcomes among those aging with HIV. Older persons with HIV do not show the same age-related declines in depression that are observed among older adults without HIV, making depression all the more relevant in this population. Additionally, research has indicated moderately high levels of overall distress among older persons with HIV, distress that is compounded by the addition of other chronic health problems. Moreover, depression in persons with HIV is associated with worse physical and mental health-related quality of life. For example, one recent study found that the correlation between depression and physical quality of life is the strongest in older persons with HIV with depression as compared to younger persons with HIV. These findings further emphasize how important it is to detect and manage depression in older persons with HIV in order to promote both mental and physical well-being.

Both antidepressant medications and psychotherapy have shown effectiveness in treating depression among those living and aging with HIV. Effectively treating depressive symptoms can lead to better everyday outcomes, including better medication adherence, sustained virologic suppression, reduced likelihood of HIV transmission, improved health-related quality of life, and longer survival. However, despite the existence of effective treatments for depression, underdiagnosed and untreated depression is highly prevalent. This is likely due to numerous factors complicating the clinical picture of aging with HIV, including individual patient characteristics, somatic symptom overlap between depression and chronic medical illnesses, and competing demands of primary care visits. Physiologic changes associated with medication metabolism that may cause symptoms that look like depression also complicate the clinical picture and care planning. Studies have found patient race/ethnicity to be a contributor to depression treatment, with depressed African American patients with HIV less likely to receive treatment than their non-African American counterparts. Additionally, investigators have found that patients with HIV diagnosed as severely depressed in a primary care setting are more likely to receive mental health treatment than patients meeting clinical criteria for mild or moderate depression. These investigators also found that if depression was not treated on the day of a patient’s primary care assessment, it was unlikely to be treated within the following 90-day period, regardless of depression severity.

It is also important to consider cohort effects when diagnosing and treating older adults living with HIV. The mental health of older adults who have been newly diagnosed with HIV will look different than the mental health of adults who have successfully survived into older age with HIV. In addition to the duration of HIV disease, individual patients may be experiencing mental health problems for the first time in their lives, or they may have a long-term history of mental health symptoms. These cohort effects impact how older adults perceive mental health problems and treatment and self-identify, experience, and describe their emotions and distress. For example, while not recognized by the DSM-5 at this time as a clinical syndrome, many older persons with HIV who are long-term survivors have what some of these patients refer to as AIDS Survival Syndrome. *AIDS Survival Syndrome* has been defined as a latent trauma response that emerges among those who survived the AIDS epidemic. These individuals represent a unique group of older persons with HIV who lived through a period of history in which they suffered the loss of many of their friends, partners, and community and were faced with the real threat of death to their own personhood. *AIDS Survival Syndrome* is thought to manifest as a cluster of symptoms including one or more of the following: depression, personality changes, flashes of anger, survivor's guilt, anxiety, emotional numbness, insomnia, social withdrawal and isolation, hopelessness, substance abuse, sexual risk-taking, and a lack of future orientation. Symptoms can range from mild to severe. While empirical evidence is currently lacking on AIDS Survival Syndrome, the authors believe this nomenclature can help clinicians understand the lived experience of this particular cohort of older persons with HIV and provide education and develop appropriate treatment plans for these individuals. Moreover, for those with symptoms of AIDS Survivor Syndrome, the term may normalize their feelings while providing a way to connect with others with similar lived experiences.

Substance Use

Prevalence rates of substance use are higher in older persons with HIV compared to their HIV-negative peers and range from approximately 20% to 50%. Substance use is a known primary risk factor for HIV medication nonadherence, particularly in those using hard drugs (i.e., cocaine or amphetamines) or people who inject drugs, or those with multiple-substance use such as combined cocaine and methamphetamine or combined cocaine and heroin. Excessive alcohol use, with and without other substance use, is also a predictor of poor adherence. A large study of substance use patterns among persons with HIV aged 50 and older found the poorest adherence and greatest self-perceived impairment from substance use among those using alcohol and cocaine/crack or those using multiple substances. Another large study examining excessive alcohol use among older persons with HIV with poor antiretroviral adherence found the following clinical characteristics to be related to the most severe unhealthy drinking patterns: African American race, less than full-time employment, alcohol treatment within the past year, and a positive depression screen. The pronounced role of substance use among older persons with HIV, together with the known negative impact of substance use on medication adherence and other functional outcomes, underscores the need for ongoing substance use screening and treatment in addition to increased prevention efforts on the part of both primary care clinicians and mental health professionals.

HIV and Severe Mental Illness

A meta-analysis published in 2016 found the prevalence of HIV among persons with severe mental illness (SMI) in the United States was 6.0% which is markedly higher than the general population (0.6%). Additionally, in African countries, the prevalence of HIV among persons with SMI was 19%. Despite these high rates, the literature on the co-occurrence of SMI and HIV is limited, particularly in older persons with HIV, but limited research does suggest that older persons with HIV and SMI, particularly psychosis, are at greater risk for mortality than with either illness alone. The association between SMI and HIV differs at an individual level and may be due to their simple coexistence or SMI preceding the acquisition of HIV. Alternatively, among those with psychosis, HIV may have a direct impact on the development of psychosis due to the effects of the virus or antiretroviral medications on the CNS.

Patients with schizophrenia, in particular, may have difficulty describing their symptoms and may be more susceptible to HIV-related distress. Clinical evaluation of older persons with HIV with schizophrenia requires a comprehensive assessment of the onset and course of symptoms. Additionally, caution should be taken when prescribing antipsychotic medications and take into account medications' side effects and interactions with antiretroviral medications.

Some evidence exists for the beneficial effects of antidepressant medication on improving antiretroviral adherence among patients with co-occurring HIV, bipolar disorder, and current mental health symptoms. For example, research examining antiretroviral adherence among patients with HIV and bipolar disorder found antiretroviral adherence was significantly better than adherence to psychiatric medications. These investigators also found a correlational relationship between antiretroviral adherence and psychiatric medication adherence, indicating increasing adherence to one medication may have an impact on adherence to the other. In other research, a disconnect between memory performance on standard neuropsychological tests, subjective memory complaints, and depressive symptoms in this population has been observed, such that memory complaints were not associated with memory performance but were associated with depressive symptoms. In turn, memory complaints were predictive of problems with everyday functioning (e.g., unemployment, dependence on activities of daily living [ADL]). Compared to persons with HIV without bipolar disorder, those with cooccurring bipolar disorder had less awareness of their actual memory abilities. Investigators concluded that both subjective memory complaints and objective memory ability should be considered when treatment planning in this subset of patients with HIV, as both appear to impact everyday functioning behaviors.

Successful Aging With HIV

To date, most studies have focused on factors associated with aging with HIV that are predictive of poor functioning, including physical illness burden, immune dysfunction, cognitive impairment, and psychiatric problems. Nonetheless, there is a growing body of literature that suggests the possibility of successful aging in individuals with HIV, and understanding HIV in this light may help identify individual factors related to a better quality of life and well-being. Studies have shown that there is a potential for successful cognitive and emotional aging among older adults with HIV, despite significant medical comorbidities and disease burden. Additionally, emerging research has shown that successful aging among persons with HIV appears to be buffered by protective psychological factors such as resilience and optimism.

There is also a rapidly growing body of healthy aging literature demonstrating the benefits of physical activity on physical and mental health and well-being outcomes. In older persons with HIV, studies have also demonstrated a positive impact of physical activity on improved physical function and lower rates of cognitive impairment. While physical activity is one of the most well-studied modifiable lifestyle factors, other modifiable lifestyle factors such as a cognitively active lifestyle, good nutrition, and sleep have also garnered attention as possible ways to improve or sustain physical and mental health among older persons with HIV.

COMORBIDITY AND MULTIMORBIDITY

As persons with HIV are living longer, they are increasingly experiencing fewer AIDS-defining conditions and a wider range of non-AIDS diseases. Some of the more common comorbidities in older persons with HIV include hypertension, diabetes mellitus, insulin resistance, cardiovascular disease, pulmonary hypertension, liver disease, kidney failure, non-AIDS cancers, osteoporosis, peripheral neuropathy, and “frailty,” which is characterized by weight loss, weakness, and increased risk of disability and death.

Although comorbidities in persons with HIV on ART are often defined as “non-AIDS,” they are associated with HIV disease (HIV-associated non-AIDS or HANA), HIV treatment, and/or behaviors, conditions, and demographics more common among those with HIV. Thus, while they are also common in HIV-negative older persons, these conditions may act differently among older persons with HIV. Several mechanisms have been suggested, including microbial translocation, chronic inflammation, oxidative stress, and immune senescence. Yet, much work remains to be done to understand the mechanisms underlying comorbidity in older persons with HIV.

Guidelines are available for the management of common comorbid conditions in older persons with HIV. It is important to bear this in mind. However, that multimorbidity is common among older persons with HIV and is more than simple comorbidity. Multimorbidity is conceptualized as the presence of several health problems that have the propensity to synergize to worsen a person’s functional capacity and increase mortality more than might otherwise seem apparent. When considering diagnosis and treatment in multimorbidity, the sum is greater than the parts. This multimorbidity can result in overlapping injury to multiple organ systems transforming HIV into a complex chronic disease. This has prompted the need for better methods to track the impact of comorbidities and multiple organ system dysfunction on the health of people with HIV.

The VACS Index was developed in this context as a tool to monitor the impact of dysfunction involving multiple organs commonly affected in HIV, using objective measures that are collected routinely in HIV clinics. It was initially published in 2013 and then was recently updated in 2019 (i.e., the VACS Index 2.0) to include additional clinical markers that improved discrimination of mortality. The VACS Index 1.0 includes age, traditional HIV biomarkers (i.e., HIV-1 plasma RNA and current CD4 count), and non-HIV biomarkers (i.e., indicators of renal and liver function, anemia, and Hepatitis C coinfection), and the VACS 2.0 added in albumin, white blood cell count, and body mass index (BMI). The VACS Index 1.0 and 2.0 have been validated for estimating the risk for mortality among people with HIV, including in diverse cohorts. The VACS Index 1.0 has also been associated with other outcomes, such as NCI, but the strength of this association is weak among Hispanics/Latinos, and more research is still needed to further examine associations with the newer VACS Index 2.0.

IMPACT ON EVERYDAY FUNCTIONING

Real-world functioning impairment is a known sequela of HIV disease, and functional disability expenditures have made HIV among the most expensive chronic illnesses. As such, the NIH Office of AIDS Research and the U.S. Senate Special Committee on Aging has emphasized the significant public health priority for research improving functioning in those aging with HIV. Real-world functioning in aging and HIV is complex and multidetermined. Age and HIV are associated with increased risk for NCI, which, along with numerous risk factors (i.e., certain demographics, depression, anxiety, memory complaints, social isolation), result in older persons with HIV having a disproportionate disruption in real-world daily functioning. *Real-world functioning* is defined as what a person actually does in their daily lives. In particular, decreases in job-related activities, self-reported problems with basic (BADLs) and instrumental activities of daily living (IADLs), worse clinician-reported functional outcomes, ART nonadherence, and driving accidents have been found in older persons with HIV relative to their younger counterparts. These age-related impairments have been found irrespective of neurocognitive status. In terms of *functional capacity*, defined as a person’s abilities that are essential to function independently in the community (i.e., what they are capable of doing, not what they actually do), a synergistic effect of HIV and neurocognitive status has been observed, such that older, cognitively impaired adults with HIV perform worse on tasks of medication management and finance management than younger and unimpaired groups.

While older age has been found to exacerbate HIV-associated disability in real-world functioning, not all older persons with HIV evidence functional impairment, which raises important questions about individual clinical characteristics impacting poor functional outcomes. The most well-studied predictor of disruptions in real-world functioning is NCI. The association between neurocognitive and real-world functional impairment is highly complex, and even subtle neurocognitive deficits, such as shallow encoding and forgetting, have been found to be associated with IADL dependence in this population. Factors believed to influence this relationship include the match between the individual's profile of neurocognitive strengths and weaknesses and the specific demands of the real-world activity (e.g., its complexity and cognitive and functional requirements). Motivation, awareness of cognitive and functional deficits, cognitive reserve (i.e., effects of enrichment of cognitive resources through educational and vocational experiences together with a person's innate intellectual ability), and the use of compensatory strategies also play a role in determining the nature of this relationship. There is also a multitude of additional static and dynamic (i.e., changes in one area may impact other areas of functioning) biologic, psychological, and social factors influencing the impact of neurocognitive ability on real-world daily functioning. For example, having sufficient home and community resources, along with appropriately adjusting daily routines to account for physical and cognitive symptoms, have been associated with successful real-world daily functioning among adults with HIV. To begin to examine these complexities, some have started to utilize technology such as ecologic momentary cognitive testing in order to examine cognition and everyday functioning in real-time in participants' natural environments. For example, one study found that doing a cognitively stimulating activity (e.g., reading a book or working) is associated with better performance on a smartphone-based executive functioning task in older persons with HIV. Moreover, this study demonstrates the utility of technology in helping to understand the complexities of everyday functioning.

Cognitive reserve may be especially important to consider within the context of aging with HIV. Research has found lower cognitive reserve is associated with risk for HIV-associated NCI and greater declines in IADLs. Conversely, higher cognitive reserve has been found to be the sole significant clinical co-factor of successful cognitive aging among older persons with HIV, whereas, among younger persons with HIV, several co-factors affecting successful cognitive aging have emerged (i.e., higher cognitive reserve, Caucasian race/ethnicity, shorter duration of HIV, and lower prevalence of lifetime alcohol dependence). Thus, the evidence suggests that among older persons with HIV, lower cognitive reserve may interfere with the adaptive ability to initiate the use of compensatory strategies when engaging in behaviors in their daily lives. Apathy and depression are also two known reliable predictors of adverse functional outcomes among older persons with HIV. A link between more severe depressive symptoms and overreporting neurocognitive and functional impairments has been identified. Furthermore, a link has also been found between less severe depressive symptoms and underreporting impairments. Associations between higher self-reported apathy with greater severity of IADL declines and more numerous cognitive complaints have been observed, suggesting that apathy may make a unique contribution to important everyday functioning outcomes. Fortunately, these risk factors can easily be screened for and are amenable to change. One rigorously designed study found no relationship between antidepressant use and better daily functioning among older persons with HIV with a current or lifetime major depressive disorder diagnosis. While, to the authors' knowledge, the relationship between antidepressant use and daily functioning among older persons with HIV has only been explored in one study, it may be important for clinicians to consider treatment incorporating a combination of pharmacotherapy and psychotherapy.

When assessing and treating functional impairments in this population, the patient's medical history, medical comorbidity burden, HIV disease burden, culture, and cohort effects should also be carefully considered. In the current era of effective ART, older adults recently diagnosed with HIV may not have the same downstream effect of HIV disease-specific biomarkers on real-world daily functioning that can be observed in older survivors; thus, disability risks may vary based on the duration of the disease. In terms of the cultural impact of age and HIV on real-world functioning, assessing the sociocultural context in which HIV occurs is important to determine factors impacting functional outcomes. These sociocultural factors may include (but are not limited to) access to health care and antiretroviral treatment, the value of employment versus disability, HIV-associated stigma, and behavioral expressions of distress.

THE SPECIAL CASE OF THE VETERAN POPULATION

The Veterans Health Administration (VHA) is the largest single provider of HIV care in the United States, with 1 out of every 250 Veterans in care at VHA living with HIV. The VHA faces challenges in meeting the needs of the growing population of older Veterans with HIV. Up to 63% of veterans with HIV have at least one mental health diagnosis, and many Veterans in need of mental health treatment are not receiving treatment. Primary barriers to treatment include identifying targets for intervention, scheduling and availability of a mental health provider, time and travel to and from a VA facility, and privacy concerns.

Older Veterans with HIV are at increased risk for depression as well as loneliness and social isolation. Depression affects over half of Veterans with HIV, making it the most common comorbidity in this population. The Veterans Aging Cohort Study found social isolation is associated with a greater risk of hospitalization and death in older Veterans with and without HIV and reported that this effect may be greater in Veterans with HIV. In a retrospective cohort study using data from the national VHA HIV Clinical Case Registry, researchers examined the impact of mental illness among Veterans with HIV on progression to AIDS-defining illness and death and found substance use to be predictive of AIDS-defining illness, whereas schizophrenia, bipolar disorder, and substance use were predictive of all-cause mortality. In summary, data from these studies indicate the need for increased knowledge of the mental health needs of older Veterans with HIV and increased access to care, specifically care targeting the aforementioned risk factors for poor outcomes.

TREATMENT AND MANAGEMENT

With longer life expectancy and improved health outcomes, it is no longer assumed that adults aging with HIV will need to collect disability payments as income. But instead, many may seek to continue working until retirement age. Given the public health burden of functional impairments associated with HIV, it is imperative to understand the risk and protective factors impacting real-world daily functioning. Additionally, it is equally important to understand these risk and protective factors in the context of sociodemographic characteristics, including sex, age, cohort effect, racial/ethnic minority status, and socioeconomic status. A targeted understanding of the most potent factors impacting real-world daily functioning at an individual level will aid clinicians in determining how and when to intervene in order to improve functioning and health-related quality of life, as well as identify functional rehabilitation interventions that can be incorporated into clinical care.

Despite the greater availability of knowledge regarding the neurocognitive consequences of HIV disease compared to the psychiatric effects, there remains a paucity of literature on treating HAND and improving overall health outcomes. Evidence has consistently shown that patients with histories of significant immunocompromise (e.g., low nadir CD4) have an increased risk of poor neurocognitive outcomes. Therefore, current practice standards recommend prescribing ART at the time of HIV diagnosis as a prevention strategy against the neuroinflammatory cascades associated with poor immune functioning. While it is accepted that people with HAND should be on ART, it is also known that certain antiretrovirals are particularly neurotoxic and, if possible, it may be best to opt for a less neurotoxic antiretroviral if it is thought this may be contributing to HAND. Unfortunately, clinical trials using neuroenhancing drugs (e.g., psychostimulants, memantine) for the treatment of HAND have been largely unsuccessful. However, treatment of other comorbid conditions (e.g., HCV infection, depression) may be beneficial. Overall, there is currently no first-line clinical pharmacotherapy for HAND among adults aging with HIV. While cognitive and behavioral rehabilitation strategies are increasingly being explored, published studies on cognitive neurorehabilitation approaches for HAND are scarce. Solely using pharmacotherapy for HAND treatment is contraindicated, as there is a strong correlation between neurocognitive deficits and medication nonadherence among persons living with HIV. Psychotherapeutic interventions incorporating cognitive and behavioral components with adherence (i.e., cognitive behavioral therapy for adherence and depression [CBT-AD]) are potentially efficacious supplements or alternatives to pharmacotherapy. Additionally, there is some promising early evidence of the potential efficacy of restorative cognitive rehabilitation approaches.

Lifestyle modification is another potential functional rehabilitation treatment approach. Evidence-based behavioral treatments exist for a vast array of lifestyle factors, including physical activity, stress reduction, mental activity, social engagement, sleep hygiene, and substance use reduction. For example, although the research is somewhat mixed, a number of studies have found that mindfulness-based interventions are efficacious in reducing depression and anxiety symptoms and improving quality of life. While most studies have not examined older persons with HIV specifically, a meta-analysis found that older age actually conferred greater benefit from mindfulness-based interventions and thus may be particularly beneficial for older persons with HIV. Although many of the aforementioned lifestyle factors have yet to be tested (via controlled trials), specifically among older adults with HIV, many of these factors protect and promote cognitive reserve, increase brain-derived neurotrophic growth factors, and reduce neuroinflammation and oxidative stress, which could have a direct benefit on cognitive and real-world everyday functioning.

FUTURE DIRECTIONS

As long-term survival among persons living with HIV continues to improve, the need for identifying personalized targets for improving outcomes in this population is clear. Comorbid health problems are the norm among persons living with HIV who are 50 years of age and older. Continued efforts to integrate primary health care, geriatricians, HIV providers, and mental health treatment are needed to address the needs of this population. Although recommended, many primary health care providers and HIV providers are unlikely to assess for HAND or mood symptoms, which have a direct negative impact on treatment. Comprehensive assessment and integrated care planning in this population, regardless of age, is necessary. It is increasingly important for the patients, their care providers, and the health care system to expand the focus of clinical research and practice beyond the alleviation of symptoms to consider issues of real-world functioning and health-related quality of life.

55.6h Technology for Seniors

AVERY QUYNH, B.S., VANESSA SCOTT, B.S., COLIN A. DEPP, PH.D., AND IPSIT V. VAHIA, M.D.

With the population of older adults expected to reach two billion worldwide by 2050, there will be a serious shortage of skilled care providers to manage the needs of this population. To cope with the increasing demands for health and social care, there is a great need to reorganize care processes and leverage different technologic solutions. Simultaneously, with the rapid maturing of the "aging in place" movement, there is an unprecedented incentive to optimize an array of technologies to help adults maintain independence in their own homes and avoid or forestall the transition to institutionalization. Over the past decade, there has been a revolution in how technology has both evolved and impacted the global population at large. Canadian social scientists Wellman and Quan-Haase used the term "hyperconnectivity" to describe multimodal human-to-human and human-to-machine interaction using a variety of platforms, including face-to-face, email, mobile phone technology, and the Internet. The implication of this term is that most persons will communicate via a multitude of channels facilitated by technology and that human interaction with multiple forms of technology will grow substantially.

In response to this societal shift, there has been an explosion in technologies over the past decade, facilitated not just by seamless communication but also by advances in computing and sophisticated sensors that can increasingly provide continuous objective data on a number of parameters. Although older adults have traditionally been considered late adopters of emerging technology, there is a growing consensus that this demographic group, with its needs for increased care and monitoring, especially among the oldest old with multiple medical needs and reduction in independent functioning, represents a significant opportunity for technology-based innovation.

COMPARATIVE NOSOLOGY

Defining Technology in Aging

The term *technology* is derived from the Greek term "*tékhne-*," which means art or skill. It is defined by the Collins English Dictionary as the "total knowledge and skills available to any human society for art, skills, etc." This is a very broad term, subject to multiple interpretations, and inclusive of technology in all its forms and considerations, from the use of flint to make fire to the latest developments in robotics. More recently, within the context of aging, researchers have favored the use of the term "gerontechnology," which has been described as "an interdisciplinary field of scientific application of technologic applications that are directed toward the aspiration and opportunities of the older person." These are broad terms, and as may be expected, they cover a very broad range of technologies. Table 55.6h–1 presents an overview and broad classification of types of technology based on application. This chapter will focus primarily on Information and Communication Technology and Assistive Technology. These terms encompass a range of approaches, such as virtual reality (VR), robotics, and tools that incorporate sophisticated data analytics methods such as machine learning. Other technologies, including Smart Home Technology, are also discussed.

Table 55.6h–1.
Classification of Technology for Aging

Type	Example	Target Population	Role
Medical technology	Pacemakers, implanted medication infusion systems, vagal nerve stimulators	Focused: Older adults with specific medical issues	Targeted medical role
Assistive Technology	Telemedicine systems, sensors (e.g., accelerometers), monitors (e.g., glucometers)	Narrow: Older adults with medical conditions that require monitoring	Maintenance of physical health and well-being
Information and Communication Technology	Wi-Fi, smartphones, tablet devices (e.g., iPads)	Broad: Older adults with need and ability to connect to the internet or use cellular technology for communication	Staying in touch with friends or family, more integrated social functioning, access to information
Smart Home technology	Personal emergency response systems (PERS), environmental sensors	Broad: Older adults with cognitive or functional impairments, invested in aging in place	Facilitating remote monitoring of older adults living independently, minimizing risk of in-home adverse events

There has been a growing cross-disciplinary effort to develop and apply information and communication technologies (ICTs) for acquiring, processing, presenting, and managing health-related data in older adults. The goal of these technologies is to improve health, quality of life, and social connectivity for less impaired older adults and assist in clinical care and monitoring of more impaired older adults. Although older adults do not use ICTs as commonly as younger individuals, they do use devices such as smartphones in comparable ways, that is, to communicate, access information (health-related and otherwise), entertainment, and financial management. Emerging data suggest that certain factors, such as the perceived advantage of technology and design issues, contribute to the lower rates of technology use in older adults. These issues may serve to guide the modification and development of ICTs tailored to engage and benefit older adults.

Assistive technologies have a more narrow scope and focused application since they are usually developed to target specific medical conditions or functional deficits. It is important to note that a specific technology may be classified in more than one category. For example, a smartphone is usually considered a platform for an ICT. However, it may be used as a form of assistive technology, if a specific app has a targeted role in monitoring. In addition, there is a new generation of cellphone accessories that aim to leverage the computing capabilities of smartphones to transform them for use as medical devices. For example, a 2016 FDA-approved device, the Steth IO, is a digital stethoscope linked to an iPhone application that can measure heart rates and listen to lung sounds. Portable and more widely accessible health devices like the AliveCore portable EKG scanner are also technologic advances in mobile medicine. Such devices have the potential to facilitate remote consultations and rapid diagnoses.

Technology and Aging in Place

An important goal of technology for older adults is to compensate for age-associated losses in physical and cognitive functioning. There is growing evidence to support the use of assistive technologies as a way to allow older adults to “age in place.” Aging in place is defined by the Centers for Disease Control and Prevention (CDC) as “the ability to live in one’s own home and community safely, independently, and comfortably, regardless of age, income, or ability level.” Social networking, remote monitoring, and assistive devices have shown promise in enhancing opportunities for aging in place. Since a significant proportion of increased health care costs associated with aging is related to the need for intensive monitoring and institutionalized care, promoting aging in place is an important approach to preserving independence and reducing costs. Both ICTs and assistive technologies have a key role in promoting aging in place. The American Association for Retired Persons (AARP), which has taken on a prominent role in advocacy for aging in place, describes case scenarios on its website of how technology, including pillbox sensors, refrigerator sensors, and personal emergency response systems (PERS) can help promote aging in place. Applications complement such technologies by offering services like organizing transportation, tracking medication, and meal assistance for older adults,

SPECIFIC APPLICATIONS OF TECHNOLOGY

Telehealth

Medical providers are increasingly using telecommunication devices in the diagnosis and care of patients in remote locations. The COVID-19 pandemic has been primarily responsible for the scaling up of telehealth to the extent that it is now a default modality for providing care in many settings, particularly in higher-income countries. These technologic modalities include video, voice, robotic, and remote-access technology to facilitate interactions between providers and patients. Telehealth approaches to observe patients and provide intervention services have direct relevance to psychiatry and geropsychiatry. The use of telemedicine demonstrates its ability to be cost-effective and improve the ease with which patients may be observed and assessed.

A large and rapidly growing body of literature supports the reliability and feasibility of using videoconferencing as an assessment modality for patients with psychiatric illnesses. Furthermore, this approach is a useful method of delivering interventions in this population and is associated with good functional and psychiatric outcomes. Studies conducted since the COVID-19 pandemic also validate the significant pragmatic benefits reported by recipients, including quicker access to providers and the convenience of not needing transportation to get care.

Building on this explosion of telecare, academic institutions, government agencies, and several privately operating companies are developing concepts, systems, and devices in a geropsychiatry context. Telehealth approaches mitigate the unique challenges faced by this population. For example, distance from providers may restrict regular health care visits for older patients with limited mobility. Services such as video consultation and remote monitoring devices facilitate the transfer of information between the patient and doctor and monitor the appropriateness of clinical interventions, thus improving the quality and access to health care. A majority of interventional telemedical studies in the geriatric population have focused on monitoring older adults. This includes routine personal monitoring accompanied by supportive contact between the health care provider and the patient and/or measurements of key biomarkers using technologic modalities. Overall, such interventions appear to have a positive impact on important health outcomes such as adherence and behavioral change.

Older patients tend to have physical and cognitive limitations and thus have distinctive needs that must be addressed by telehealth protocols. It is particularly promising that telehealth approaches appear to be feasible and useful in a wide variety of geriatric subgroups. For example, Loh and colleagues developed and examined a videoconferencing protocol for diagnosing Alzheimer disease and found that there was good diagnostic agreement between the telemedical modality and the face-to-face assessment. Telepsychiatry has also been investigated in nursing home populations. Not only do telepsychiatry visits have a positive impact on the quality of patient care, but they also appear to be associated with significant financial savings (approximately $30,000 saved over the course of 278 telepsychiatry visits). During the COVID-19 pandemic, it became increasingly difficult for older adults to receive care due to physical and social distancing restrictions. However, the rise of telemedicine allowed patients to get the care they needed without having to leave their homes. Studies performed using telemedicine with adults with dementia showed the feasibility and overall acceptance of these methods of health care. Taken together, these data support the potential benefit of telemedical applications in aging cohorts and highlight the need for greater empirical attention to the development and use of these novel approaches.

The application of telehealth concepts to geropsychiatry requires attention to the clinical benefits of these approaches, as well as their feasibility, acceptability, and cost–benefit ratio. As these systems spread in use, it is worthwhile to consider whether demographic factors (e.g., age, gender, race, level of education, and employment status) impact the ease with which older adults use these telehealth modalities. Furthermore, the influence of factors such as dementia, psychiatric illness, and caregiver availability also needs to be better characterized. These variables can guide the efforts to maximize the usability and acceptability of telehealth interventions in older adults and, potentially, subsequent public policy.

Telemedicine-based approaches also continue to find application in providing clinical services in underserved areas, and one of the major consequences of the COVID-19 pandemic has been the explosion of ways in which telemedicine-based mental health services are accessible. Beyond video-based interactions between providers, services such as guided therapy apps, mindfulness programs, and chatbots have all found niches that expand the offerings and availability of mental health care, even in remote areas. A challenge for the future will be to ensure that there is equity in how telecare is provided and ensure that older adults without access to technology or a lack of proficiency in its use are not left behind.

Mobile Health

The term *mobile health* (or mHealth) loosely refers to the use of mobile phone technology for health care. In the past 10 years, there has been an explosion of interest in the uses of mobile devices in collecting health-related data, delivering health care, and facilitating interaction among patients, clinicians, and family stakeholders in the service of improving health. There are several reasons why mobile phones are specifically attractive as a potential platform for health care delivery. For one, recent estimates indicate that the penetration of mobile phones is approximately 90% in the United States. This penetration has increased at a rapid pace over the past 10 years and is nearing complete saturation. Older adults are, as with other technologies, less likely to own a mobile device than their younger counterparts, but as of 2014, 74% owned a mobile device. A review of 28 studies by Wilson and colleagues found that while older adults experienced some barriers to smartphone use (e.g., being a “digital native,” sensory or motor problems with interaction), smartphones and tablets were central to the lives of older adults sampled. The use and ownership of cell phones cut across other sociodemographic strata, with poor and underserved subpopulations often more likely to rely on mobile devices. This ubiquity of mobile devices provides a remarkable new conduit for innovation in health care delivery, and both academic and consumer developers have responded with the creation of a wide variety of mHealth applications.

The “value proposition” of mHealth is that it could enable delivering care outside of the typical clinic setting, either by augmenting interventions by providing additional interaction to support everyday health-sustaining behaviors (e.g., medication adherence) or by extending them beyond the time frame typically associated with the intervention. Remote mobile technologies can automate tasks that are typically performed by clinicians, such as appointment reminders, symptom and risk assessments, and scheduling, which could increase access to health care by reducing the need for face-to-face interaction. Additional benefits of mHealth are the ability to help compensate for prospective memory problems and facilitate the self-management of chronic illnesses. Mobile phones can provide timely reminders for beneficial health behaviors and deliver “just-in-time” interventions that could diminish the time gap between symptom emergence and intervention. Given that large volumes of data are available both through patient reports and sensors linked with the devices, it may also be possible to identify actionable patterns of symptoms over time in chronic recurrent illnesses and then intervene based on accumulating knowledge of individual patients so as to personalize care to individuals. Finally, provider-facing applications may assist in managing patient needs and diagnoses, reducing the need for brick-and-mortar clinic settings, which may be particularly attractive in the developing world. To temper enthusiasm somewhat, while collectively, these advantages offer great potential, the mHealth field is nascent, and so few mHealth interventions are yet embedded in routine care.

mHealth interventions typically involve a number of elements, which include the following: (1) a patient-facing platform. This is an interface that provides interaction, and typical platforms include the feature phone that is not connected to the Internet yet capable of voice or SMS interaction, a smartphone, or a dedicated device that is developed for the mHealth intervention, (2) one or more active communication channels to the patient, which may include SMS, live or asynchronous voice, email or in-app interaction. Alternatively, communication can involve passive sensing, or the collection of data without the need for patient response. Sensors are highly varied but could include activity measured by GPS antenna or accelerometer embedded in the device or ancillary sensors that couple with the device, such as blood pressure or glucose, (3) a set of algorithms that govern the interaction between data captured on the device and a clinical response. These may be automated and do not involve direct clinical oversight or might flag or prompt interaction from clinicians tasked with monitoring the incoming data, (4) a server that stores and allocates interactive elements to individual users in the intervention network, and, finally (5) a clinician facing dashboard or utility that enables a supervising clinician the capacity to manage, monitor, and interact with patients in the mHealth intervention. Many iterations of the above architecture are possible, with some apps that are completely consumer-facing without clinician oversight and others offering complex layered interaction with a variety of clinicians and other technologic assets such as the electronic medical record.

A number of reviews have addressed the question of whether mHealth interventions are effective. To date, the evidence is mixed. While recent systematic reviews have indicated that mHealth interventions seem effective for certain commonly researched areas, in particular smoking cessation and HIV medication adherence, other areas were limited in terms of evidence. A key limitation of the literature is the lack of high-quality randomized clinical trials. Very few of the applications that have actually been subjected to rigorous randomized trials are actually available to consumers. As such, the mHealth field is somewhat bifurcated into unproven apps directly available to consumers and academic products that are not translated to products available to consumers.

mHealth solutions for mental health and aging are far fewer in number than are ones for chronic medical illness. Nonetheless, there are some examples of apps designed for chronic mental illness, including schizophrenia, bipolar disorder, and substance abuse. Review studies have indicated that mHealth applications could provide important resources to support access, initiation, engagement, and sustainment of psychiatric care. A study published by Depp and colleagues indicates that even among older adults with schizophrenia, the rate of past exposure to mobile phones is high (78% had ever used one), and the great majority felt comfortable with the use of mobile devices. Despite high rates of prior use, few patients currently own mobile devices, which creates a barrier to future implementation without subsidization of mobile devices. Moreover, data gathered by mobile devices on symptoms appear to be valid—one study indicated that daily mood ratings obtained in a sample of patients with bipolar disorder appear to be more consistent with clinician ratings than were identical mood ratings recorded on paper-and-pencil forms. As such, evidence, albeit limited, suggests that patients with chronic and severe psychiatric impairments are capable of using mobile devices and can report accurately on symptoms that would be the likely focus of intervention.

There have been few randomized trials of mHealth interventions in psychiatric illnesses. Depp and colleagues conducted a 24-week randomized controlled 81-patient trial of a four-session psychoeducational intervention for bipolar disorder augmented by automated personalized reminders contrasted to a four-session intervention without mobile device augmentation. Effect sizes for this trial indicated that the mobile augmented condition was associated with a greater reduction in depression by a medium effect size; the magnitude of this effect is notable given the challenges met by many interventions in impacting bipolar depression. However, these positive effects seemed to dissipate at follow-up, suggesting that gains made by mobile augmentation were not sustained once mobile intervention ceased. Separate studies by Granholm and colleagues, as well as Ben Zeev and colleagues, have each reported positive changes in medication adherence, psychiatric symptoms, and socialization in open trials of SMS and smartphone application interventions in schizophrenia. In addition, Depp found in an adjacent study that a similar population will self-initiate mobile intervention even when not prompted to engage. Gustafson and colleagues evaluated a smartphone application designed to extend the impact of rehabilitation for alcohol use disorder and found significant reductions in alcohol use in a randomized trial of more than 300 patients. This was later supported in a follow-up study led by Mckay assessing a phone call versus application intervention, in which both were effective but not any more powerful when combined. As such, these emerging clinical trials offer an encouraging indication of the feasibility, acceptability, and effectiveness of mobile interventions that augment psychiatric care. Given the large number of ongoing clinical trials of mHealth interventions in mental health conditions (see ClinicalTrials.gov), it is likely that data on the effectiveness of mental health targeting mobile applications will proliferate in the near future.

There are a variety of exciting and emerging directions for mHealth mental health applications. For one, there is increasing evidence that passive sensors (described in detail in the next section) can identify patterns consistent with a change in symptoms. For example, vocal prosody appears to covary with mood symptoms in bipolar disorder. If passive sensors can supplant patient reports, it may be quite possible to efficiently monitor and allocate preventative care to patients without the need for patient-initiated interaction. Second, and relatedly, there is increasing interest in the use of predictive analytics in leveraging the intensive longitudinal data generated by mHealth applications to develop dynamic, personalized risk profiles for serious adverse events like suicide. Thompson and colleagues reported preliminary data on a statistical technique called functional data analysis that is optimized for the noisy repeated data that are generated in mHealth and found that a simple algorithm modeling negative affect highly accurately predicted subsequent increases in suicidal ideation in a small sample of bipolar patients. Other approaches have used natural language processing to identify patterns predictive of suicide. Other frontiers include the use of more sophisticated algorithms to intervene with patients depending upon social contexts or the enlistment of social networks and peers in managing mental illnesses. As with mHealth in general, while exciting, each of these novel approaches would need to be adequately evaluated in well-designed clinical trials to move beyond proof-of-concept stages to translate to impact on psychiatric care.

In summary, the field of mHealth is a rapidly evolving one that, while yet to fully deliver on its promise, holds great potential for impacting the landscape of mental health care in older adults with psychiatric illnesses. Globally, older adults are increasingly adopting mobile technologies, and the development and tailoring of mHealth interventions to meet the needs of older adults will be a subject of research for years to come.

Sensors/Self-Monitoring Devices

With accelerometers available readily, monitoring of movement, behavior, balance, as well as physiologic variables such as heart rate and oxygen saturation is becoming simpler. Researchers are developing sensors that can perform blood tests by connecting through ports to the computing chips in cell phones. Qualcomm—a San Diego-based communications company—had initiated a competition encouraging developers to produce a “tricorder,” a noninvasive handheld diagnostic device that can monitor multiple physiologic functions and perform diagnostics without the availability of sophisticated labs. In 2017 the winning Final Frontier team created DxtER, an AI engine used to diagnose medical conditions using noninvasive sensors that collect vital signs and other biometrics.

Table 55.6h–2 outlines various types of sensors and the types of roles they can play in promoting aging care.

The use of sensor technology in health care especially for older adults, is a rapidly evolving field. Wrist-worn and body-worn accelerometers have found multiple uses in health care to infer behavior from physical activity. Most of these sensors rely on accelerometry to detect motion. However, the new generation of sensors can utilize more sophisticated approaches, such as computer vision or radio sensing, to extract markers of behavior from large quantities of data.

Chemical sensors and body-worn sensors are noninvasive alternatives that have shown promise in vitro testing. These sensors can be easily produced on a mass scale using 3D printer technology and can be mounted on a variety of platforms such as mouthguards for measuring electrolytes and metabolites in saliva), textiles (for measuring sweat or urine), bandaids (for measuring chemicals in interstitial fluids). These sensors can also be integrated with microneedles that are minimally invasive and painless. Currently, sensors in development can measure a wide range of electrolytes and metabolites, including glucose, lactate, sodium, potassium, pH, and urea.

Wearable sensors can already measure vital signs, and commercially available devices such as the recently launched Apple Watch can measure and transmit heart rate in real time. These sensors have led to the creation of novel “personal health data.” Philips Respironics developed the Actiwatch Spectrum, an actigraphy device that measures daily activity as well as sleeping patterns. Several health care systems are working on developing infrastructure that can incorporate such data with electronic health records to have a more complete set of data on patient health and well-being.

Wireless electroencephalography (EEG) devices are also gaining popularity. These devices consist of a semicircular band with electrodes on either end, which can be placed bitemporally to collect bitemporal EEG readings. These devices are also being utilized to gather EEG data to predict emotional states, pain, and anxiety.

As the use of wearable devices and sensors grows, there is a need to develop algorithms that can generate relevant clinical alerts based on changes in physiologic and environmental data. Further, medical providers, caregivers, and the wearers themselves will need tools to visualize these data and use that information to predict or respond to abnormal events.

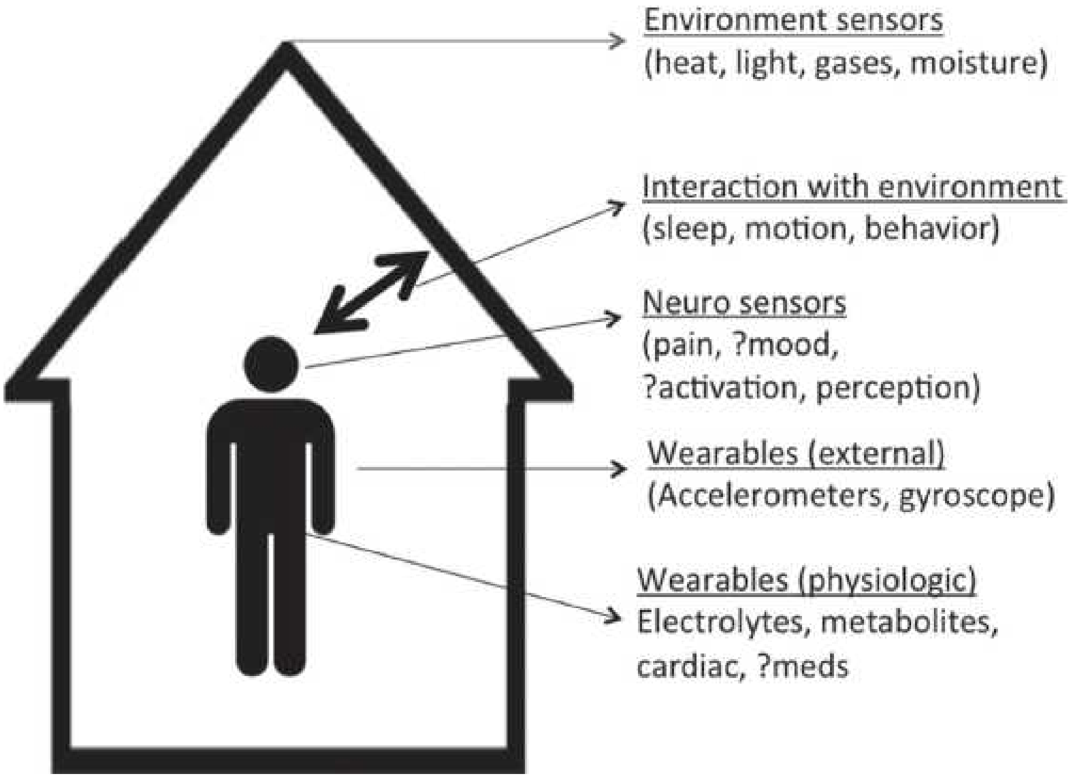
Table 55.6h–2.
Classification of Sensor Technology

Type of Sensor	Examples	Role	Stage of Development (at time of writing)
Implantables	Nanosensors	Monitoring of parameters in very constrained environments, e.g., small blood vessels, GI	Conceptual development and prototyping. Clinical validity not yet established
Neurosensors	Bitemporal EEG monitors	Portable noninvasive monitoring of neurologic (e.g., seizures), psychiatric (e.g., anxiety), and physiologic (e.g., pain) parameters	Commercially available. Clinical validity under assessment
Wearable physiologic monitoring devices	Microneedle-based sensors, tattoo sensors	Noninvasive monitoring of electrolyte and metabolite levels	Prototypes developed. In-vitro device validity and reliability under assessment
Wearable external monitors	Accelerometers, gyroscopes	Monitoring of psychical activity patterns and sleep	Commercially available and clinically validated

Environmental sensors	Motion sensors, gas sensors	External continuous monitoring of activity and functioning	Motion sensors are currently commercially available. Gas sensors are in prototype stage

Smart Homes and Senior Design

Advances in ICT have led to a growing interest in the development of “smart homes,” that is, living environments equipped with multiple sensors that can monitor and detect a person’s activity. The goal of these technologies is to improve the quality of life and promote the physical independence of older adults. Within this context, multiple devices and technologies may be embedded within the infrastructure of the residence and may thus function without the need to train residents on their use. For example, a heat sensor mounted on a stove can detect if the stove has accidentally been left on for a prolonged period. Motion sensors can keep track of a person’s mobility in the house and may provide information on clinical issues such as triggers of insomnia and markers of agitation such as pacing. Au Yeung and colleagues utilized passive environmental sensing techniques to monitor the behaviors of patients with late-stage dementia. They used a combination of motion sensors, actigraphy devices, and bed pressure mats to monitor the behaviors of older patients with dementia in assisted living facilities and found that passive environmental sensing techniques can help monitor patients without obstructing their daily activities and help providers adjust the patients’ medications based on their activity. Existing prototype smart homes (e.g., the Awarehome at the Georgia Institute of Technology) serve as research environments that guide the development of technologies that may aid the development of senior-friendly living. Smart homes may be beneficial for individuals living alone who are unable to seek help in emergencies (e.g., falls, strokes, unconsciousness), older adults with cognitive (e.g., memory loss, visuospatial deficit) and/or physical (e.g., hearing, visual, or mobility) impairments, and individuals needing assistance in performing basic and instrumental activities of daily life. Additionally, smart homes may provide integrated telehealth tools that can connect people living in rural or underserved areas with medical providers. With regard to the use of smart homes, important questions such as health outcomes, clinical algorithms for predicting potential health problems, user perception and acceptance, and privacy issues are yet to be fully addressed. Ideally, a smart space, depicted in Figure 55.6h–1 for health monitoring, should be able to integrate implanted, body-worn, and environmental sensors to measure changes in the individual's body, their behavior, and changes in the environment. Such a space would also incorporate mHealth approaches (described above) and machine learning and big data analytics (described below) to generate relevant health information with the capability to be predictive of health events. Smart home technologies are also increasingly being deployed in settings such as Assisted Living facilities and dementia care facilities to facilitate a higher level of monitoring without increasing the need for human resources.



Environment sensors
(heat, light, gases, moisture)
Interaction with environment
(sleep, motion, behavior)
Neuro sensors
(pain, ?mood,
?activation, perception)
Wearables (external)
(Accelerometers, gyroscope)
Wearables (physiologic)
Electrolytes, metabolites,
cardiac, ?meds

FIGURE 55.6h–1. Smart room. This figure indicates the multiple parameters of interaction between persons and their environment that can be quantified by sensors. This figure includes both existing and in-development sensor technology.

PERS are another set of important applications of ICTs. These are relatively inexpensive devices designed to facilitate emergency responses for older adults. They may reduce mortality rates and hospital utilization and may be especially useful in rapid detection and early response to falls, and the use of this technology is a subject of great interest and study.

Overall, it remains to be seen how sophisticated home-based solutions and the growing number of advanced ICT applications are tolerated and utilized by older adults in general and specific groups such as those with disabilities or dementia.

Games

Interest in clinical and cognitive applications of video games and game-based interventions continues to grow.

Broadly, computerized games can be classified into one of four types:

- Games developed for or played on commercially developed gaming systems such as the Sony Playstation, Microsoft Xbox, or Nintendo Switch
- Commercially available cognitive games such as Lumosity or Posit Science modules
- VR games
- Games developed for research purposes

In one study conducted by Rosenberg and colleagues in 2010, researchers utilized the Nintendo Wii system, which relies on the persons using the system to perform physical tasks, and administered an intervention of physical exercise conducted indoors to assess improvements in subsyndromal depression in older adults. In a small sample of 19 patients, they noted that exercise using this game, performed for 35 minutes three times a week, resulted in statistically and clinically significant improvements in depressive symptoms.

Several cognitive games have been marketed in the past 10 years, aimed at improving cognitive function in older adults who have experienced cognitive decline and also at younger adults who are cognitively intact but invested in maintaining a high level of cognitive function. However, evidence of the efficacy of such games remains mixed. Despite early promise, large meta-analyses of data from studies of such games indicate that, at best, they may result in some domain-specific improvement in the cognitive abilities specifically targeted by each game. However, there is no evidence so far to suggest that such gains may be more generalizable to other domains.

There is also existing evidence of the efficacy of a game that was custom-developed to require multitasking. This game—a 3D racing game called Neuro Racer—was administered to older adults, and the authors noted that by performing the multitasking required by the game, older adults demonstrated benefits in multiple cognitive domains, including those such as sustained attention and working memory, which were not targeted by the game. Moreover, the resultant cognitive enhancement persisted for up to 6 months. This study provides a counterpoint to previous studies on cognitive games and suggests that rather than targeting specific domains, games that tap multiple skills may be efficacious in improving cognitive outcomes. More recent studies are examining how gamification-based therapeutic approaches can increase adherence and stimulate brain changes that can lead to improvement in depression.

In a 2019 systematic review, Skurla and colleagues highlight the saliency of using VR in aging adults experiencing disorders or impairments as an alternative approach to traditional cognitive measures, interventions, and training. The culmination of existing VR literature from 2008 to 2020 suggests a need for creating standardized VR simulations to use in future research. The feasibility of using VR to measure cognitive impairments across publications yields promising results and has value for utilizing more life-like ecologic assessments within laboratory settings. For example, a grocery store simulation task can evaluate things like working memory, spatial cognition, or daily living activities within the safety of a laboratory setting. Generally, this review emphasizes that studies found significant differences in VR cognitive assessment tasks between healthy and impaired samples. Additionally, VR studies could distinguish different cognitive domains, suggesting the possibility of future VR diagnostic elements. Given the increased availability of this technology and its shift from computer-mouse simulation to headset and navigation technology, there is a lot of room for innovation in using this as a research methodology in the future.

Overall, the use of a computer gaming interface has been found to be an acceptable and enjoyable method for a wide range of tasks and tests for older adults. Given the ease with which games can now be accessed on ICTs, this application is likely to grow rapidly over the coming years.

Tablets

Given the larger screen and the consequent versatility of the touchscreen, tablets are increasingly being used for a variety of applications in older adults.

Several existing cognitive screening tools and other performance-based standardized tests are being adapted to iPad versions, including the UCSD Performance Skills Assessment. Clinical applications, especially for comprehensive neuropsychological testing using tablets as the platform for administration, are beginning to gain acceptance. A study by Mielke and colleagues has demonstrated that the use of iPad tablets may be especially acceptable to older adults and that testing scores are comparable to those from regular pen-and-paper testing. With the proliferation of telemedicine, device-based health care, including testing, is gaining vogue for older adults.

In addition to applications developed for delivery using tablets, there is evidence that simply learning to use a tablet device may be beneficial. Older adults are believed to be more receptive to learning these devices over computers because of larger screens, intuitive interfaces, and touch screens. Learning to use an iPad may result in improvement in cognitive domains, including episodic memory and processing speed, though there is no evidence it can improve visuospatial function. Programs created for teaching older adults to use technology, including tablets, may also promote well-being by enhancing intergenerational activity and new learning. In one study, Kamat and colleagues demonstrated that iPads may be effectively used to control behavioral symptoms in older adults with dementia. In this study, the authors noted that because the iPad is a versatile device that can be used as a platform for a broad range of tasks, it may be an especially effective mechanism for administering nonpharmacologic interventions. Its primary advantage would be the ability to administer multiple interventions (e.g., reminiscence through pictures, music therapy, alternative engagement through videos, and cognitive stimulation) using a single device.

Social Media

Older adults are the fastest-growing segment of users of social media such as Facebook; this population is increasingly leveraging this technology to remain connected with family and friends. A 2021 survey by the Pew Research Center found that 50% of adults over 65 use Facebook. Additionally, 45% of this population also uses social media in general, such as Instagram, TikTok, Snapchat, and Facebook. There is growing interest in creating Facebook interfaces that are simplified to facilitate use by older adults. Improving social connectedness among older adults can have a broad range of implications for enhancing well-being. The behavioral and psychological correlates of social media use in older adults warrant close empirical attention.

Caregiver Applications

ICT applications have the potential to be useful not only to older adults but also to their caregivers. These tools include peer networking, professional support, and resource identification. One innovative intervention for caregivers utilized a computer-mediated, automated, interactive system to reduce caregiver stress and aid with managing disruptive behaviors exhibited by patients with Alzheimer's disease. While these applications are promising, given the rising number of people serving in caregiver roles, the outcomes associated with these technologies are yet to be fully characterized.

FUTURE DIRECTIONS

Robotics and Nanotechnology

With the rapid growth of technology, there has been a greater emphasis on developing robotic devices that can take over many physically demanding tasks of daily life. Promising ICT applications such as robotic-assistive devices for activities of daily living and other voice-activated technologies have been receiving greater attention for their potential use to reduce the physical demands of daily activities such as cooking, but further research is required to examine how they are suited for the needs of older adults. Robotic devices may even be implantable or flexible and wearable and may play an assistive role in limb or organ function. Similarly, nanotechnology, which is growing rapidly, is considered a modality for intervention at the cellular level for aging-related disorders, especially those related to telomere dysfunction, reversal of oxidative cellular damage, and fabrication of stem cells and stem-cell–based therapies.

In addition to approaching robotics as a means of physical health, research surrounding social robots is exploring this technology and its utility in social interaction and mental health intervention. A 2021 review explored the potential for social robots in geriatric mental health as social companions, means of social interaction research, possible intervention mediums, and more widescale daily living utility. By investigating how humans interact with robots' researchers may identify how to optimize these relations for mental health interventions. The capacity for programming robots to identify emotions, collect speech patterns, and provide a social companion is an intriguing solution to things like increased independence in older adults and complements existing mental health support.

Big Data

Big data is a broad term used to loosely denote large volumes of data, whether collected in a structured or unstructured manner, that can be mined and analyzed for information. The rise of big data has paralleled the development of sensor technology and rapid real-time analytics. As sensors allow one to collect extremely large volumes of behavioral and other data in real time, big data analytics will be essential to allow for rapid, effective analysis of this data to generate information and decision-making. Big data analytics are also likely to play a key role in developing applications aimed at the prediction of health events and preventative medicine.

BARRIERS AND LIMITATIONS

Although there have been significant technologic advances, older adults continue to experience barriers to using technology effectively. These include inadequate training to use the devices, lack of knowledge about the technologies available, inadequate design and equipment suitability, and cost/payment issues. Some of these are reviewed below.

Integration With Health Care System

Despite rapid growth and interest in technology and aging, significant issues persist. For technologies that involve gathering personal health data, there remains incomplete integration with electronic health records. As a result, physicians often view such data (e.g., accelerometer data, sleep data) as burdensome as it involves the additional step of accessing, processing, and interpreting data. However, several companies that develop electronic medical records (e.g., Epic) are in the process of developing health apps that integrate with patients' electronic medical records. Manufacturers of commercial health care monitoring devices are also in the process of establishing ways for smoother integration of device data health with records.

Ultimately, it is likely that personal health data will be automatically integrated with electronic medical records as a routine procedure, allowing physicians to review both sets of data simultaneously.

Billing

The ICT applications for older adults hold great promise for the improvement in their quality of life and physical wellness. However, these technologies are often prohibitively expensive. In the United States, a large number of assistive technologies are not reimbursed by public or private insurance systems. The prospect of restricted payment hinders the development and widespread use of technology by those who can benefit from it the most. Congress and the Federal Government may promote the use of health technologies by incentivizing their use by providers and changing the policies regarding reimbursement through the Medicare program.

Literacy and Usability

Although ICTs have considerable potential for benefit in aging contexts, literacy, and physical limitations may pose a barrier to their utility in this population. Unsurprisingly, older adults' perceptions regarding the usability of ICTs appear to be related to their acceptance of technology. Factors such as perceived usefulness, perceived ease of use, and subjective norm have a strong impact on older adults' acceptance and use of ICTs.

Privacy and Ethics

Privacy concerns regarding the data generated by wearable and environmental monitoring systems have a significant bearing on the motivation of older adults and their caregivers to adopt these technologies. The security of these data is often trusted by a third party, and this may be associated with real or perceived disadvantages, which at present are not well characterized.

Information Overload

Although the large volume of data generated from wearable sensors and smart home devices is central to the appeal of these technologies, there are important issues that warrant consideration. The devices available tap different modalities (e.g., gait, skin conductance, diet, sleep) and provide heterogeneous longitudinal data. There is no consensus regarding the best methods to appropriately aggregate, analyze, and interpret the data collected. Episode Discovery, an unsupervised algorithm, has shown early promise in monitoring the health of older adults and identifying unusual or dangerous changes in behavior. Algorithms such as this are yet to be fully characterized with clinical populations.

Age-Related Impairments

Declines in working memory, attention, and processing speed commonly accompany normal aging. These age-related declines in cognition have important implications for technology access and use in older adults. For example, training older adults to use new platforms or technologic skills may be impacted by declines in working memory and attention, while their ability to discriminate and select targets from complex displays may be impacted by declines in information processing skills. These are important aspects that warrant close consideration during the development of technology for older adults.

Lack of Regulation and Evidence

Sensors and other health care devices remain both understudied and unregulated. Although the FDA is stepping up its effort at monitoring health sensor technology, significant work will be required to establish the safety, validity, and reliability of these devices before they are widely deployed. A further issue is that despite a recent wave of technology targeting older adults, the majority of these technologies are developed by technology firms and marketed without sufficient evidence to establish the safety, efficacy, reliability, and validity of these devices to perform the tasks they are designed for. There is a great need for data on how these technologies are used and how effective they may be. Geriatric psychiatrists have a great opportunity to be leaders in the area of establishing parameters for technology use and development in medicine.

55.6i Positive Psychiatry of Aging

Barton W. Palmer, Ph.D., and Dilip V. Jeste, M.D.

There is a growing recognition that medicine should encompass not only the treatment of symptoms but also the promotion of well-being. For geriatric psychiatry, this means greater attention to the promotion of “successful aging” as well as to other aspects of well-being among older adults. The notion that mental health is more than the absence of symptoms or disorders is not new. In 1946 the World Health Organization (WHO) published a definition of *health,* which was not merely the absence of disease or disability, but rather “a state of complete physical, mental, and social well-being.” While seemingly self-obvious, this definition is potentially revolutionary in its implications for the practice of geriatric as well as general psychiatry. Yet, approximately 75 years later, the implications of that revolution have still not become fully weaved into mainstream psychiatry. Contemporary geriatric and general clinical psychiatric practice and training remain primarily restricted to the diagnosis and treatment of mental illnesses, while psychiatric research mainly focuses on elucidating the underlying pathology and ameliorative interventions to treat and prevent relapses of mental illnesses. Within the field of Positive Psychology, founded in the late 1990s by Martin Seligman and colleagues, a growing body of research strongly suggests that positive psychosocial factors (PPSFs) such as resilience, optimism, and social engagement are associated with higher levels of subjective well-being as well as lower morbidity and greater longevity. With the founding of positive psychiatry approximately 10 years ago, subsequent psychiatric research has shown the association of PPSFs with better well-being, lower morbidity, and longevity also generalize to those living with serious mental illnesses. Although many key questions still need to be addressed through empirical research, the last decade has finally brought together the empirical foundation for positive psychiatry as a potentially key aspect of 21st-century psychiatry.

DEFINING POSITIVE PSYCHIATRY

Positive psychiatry is the science and practice of psychiatry that seeks to understand and promote well-being through assessment and interventions aimed at enhancing behavioral and mental wellness. As a part of psychiatry, itself rooted in the field of medicine, positive psychiatry is grounded in biology and ultimately seeks to determine the neurobiologic underpinnings of the PPSFs associated with positive outcomes and to use that information to develop more effective biologic and psychosocial preventive, therapeutic, and rehabilitative interventions. As a branch of medicine, an important facet of positive psychiatry that at least partially distinguishes it from the complementary field of positive psychiatry is that it is primarily focused on the promotion of PPSFs and positive outcomes among those with or at high risk for psychiatric or physical illnesses.

HISTORY

In 1906 William James, a physician and psychologist by training, spoke of the need for a new approach to psychology that would study and apply principles underlying the success of the “mind cure.” The concept of *mind cure* referred to the purported healing powers of positive emotions and beliefs. Although in retrospect, the mind-cure movement itself appears an anachronism of questionable validity, James’s emphasis on positive emotions and beliefs illustrates an early effort to include PPSFs during the emergence of psychology as an independent field. Yet these inclinations were largely neglected until the mid-20th century, which brought the Humanistic Psychology movement of Abraham Maslow and colleagues. Their focus was on the study and promotion of health and creativity among individuals. But that movement also failed to fully shape psychiatry, as well as mainstream clinical psychology. Instead, positive psychiatry traces its most immediate lineage and debt to the Positive Psychology movement initiated by Martin Seligman and colleagues in the mid to late 1990s. In his 1998 Presidential Address, Seligman spoke of the need for “a reoriented science that emphasizes the understanding and building of the most positive qualities of an individual: optimism, courage, work ethic, future-mindedness, interpersonal skills, capacity for pleasure and insight, and social responsibility.” In the ensuing decades, Positive Psychology has grown and flourished into an international movement, but much of the research has focused on promoting well-being among the psychiatrically and physically healthy, and it has had less impact on the day-to-day practice of clinical psychiatry. This situation began to change over the past decade. In his May 2013 address as President of the American Psychiatric Association, Dilip Jeste commented “I expect that the future role of psychiatry will be much broader than treating psychiatric symptoms. It will seek to enhance the well-being of people with mental or physical illnesses. That is positive psychiatry.” positive psychiatry is allied with and partially overlaps with Positive Psychology in concepts and goals, but also complements in that psychiatrists are first trained as physicians, an applied biologically rooted profession focused on treating diseases and disabilities.

POSITIVE MENTAL HEALTH OUTCOMES

There has been a growing recognition that medicine should encompass not only the treatment of symptoms but also the promotion of well-being. Similarly, the goal of psychiatric interventions should not be just a reduction in psychopathology but also the promotion of positive mental states. Some of the better-known outcomes are summarized below.

Successful Psychosocial Aging

There is no single consensus definition of successful aging. A 2006 review of the empirical literature revealed 29 definitions in 28 published empirical reports. But there were some common themes. Traditional notions of successful aging have emphasized how much one has not aged, that is, the relative absence of physical, cognitive, and social disability. However, more recent studies focused on the perspectives of older adults themselves showing that self-perceived successful aging is not dependent on physical health. Large proportions of older adults with chronic physical illnesses, who would not meet objective disability-based criteria of successful aging, perceive themselves as aging successfully. Qualitative studies indicate that older adults consider the ability to adapt to circumstances and a positive attitude toward the future as more important than an absence of physical disease and disability. This distinction between physical disability and self-perceived successful aging may help explain a now well-documented paradox of aging. Specifically, while physical health and functioning, as well as some aspects of cognitive performance, tend to decline with increasing age, subjective well-being begins a steady improvement from youth that continues into old age.

Other Positive Outcomes

Well-Being. Echoing the WHO definition of health, positive psychiatry construes *well-being* as representing the presence of pleasant, positive experiences, and states such as life satisfaction and happiness (hedonic well-being), as well as eudemonic well-being, including a sense of purpose or meaning in life and self-acceptance. The concept of well-being has risen to prominence in recent years in economics, with self-reported well-being considered a measure of national development alongside traditional constructs such as the gross domestic product. Well-being is associated with better health outcomes and with reduced mortality/greater longevity.

Low Perceived Stress. The concept of stress has a complex history; the term may be used to refer to objective pressure or tension or the body's objective response to demands or change. In the context of positive psychiatry, however, the emphasis is on the individual's perception of stress, which appears to be a better predictor of deleterious changes in some biomarkers, such as telomere length, than objective stress. Perceived stress specifically represents the degree to which individuals perceive demands, problems, or challenges as exceeding their ability to cope with them. Recurrent unhealthy stress responses lead to cumulative wear and tear.

Post-Traumatic Growth. The link between severe stress and post-traumatic stress disorder (PTSD) is self-evident but not inevitable. Some people who experience significant traumatic events experience a form of personality growth that is referred to as *Post-Traumatic Growth*. It is characterized by an increased appreciation of life, altered priorities, closer interpersonal relationships, a greater sense of personal strength, and/or recognition of new possibilities for one’s life. Post-traumatic growth is fostered by the individual’s resilience in the face of severe stress–it is not the opposite of PTSD, as they may be copresent within the same individual in response to the same stress or trauma.

Recovery from Serious Mental Illnesses. Contemporary empirical data paint a brighter picture of the course of psychopathology and disability among older people with serious mental illnesses than traditional conceptualizations. For example, relative to their younger counterparts, older adults with schizophrenia tend to have better psychosocial functioning, including better adherence to medications and self-rated mental health, and a lower prevalence of substance abuse and psychotic relapse. There is no consensus definition of recovery (e.g., there are differences of opinion regarding the need for full symptom remission), but there is a general consensus that recovery involves decreased functional dependence and reduction of the impact of the illness on one’s life. Elyn Saks has described this capacity as finding “wellness within illness.”

Prevention. Prevention is one of the key positive outcomes of positive psychiatry. The focus on prevention has long roots in community psychiatry, where there have been efforts directed at primary, secondary, and tertiary prevention. In recent decades, medicine and psychiatry have experienced a paradigm shift from an almost exclusive focus on treating pathology to promoting health, as well as from caring for individual patients to enhancing the health of communities through preventive measures. Prevention is no less meaningful in the context of geriatric psychiatry. A wealth of empirical data indicate that prevention in later life can be practical and cost-effective.

Prevention can occur at multiple levels.

a. Primordial: Strategies aimed at altering partially malleable risk factors such as social determinants of mental health like social isolation and discrimination can prevent or at least delay the occurrence of depression.
b. Primary: Treatment or prevention of depression following stroke, myocardial infarction, and/or bypass surgery results in significant reductions in morbidity and mortality.
c. Secondary: Examples include prevention of suicides following successful treatment of suicidal behavior (suicide attempts); prevention of PTSD with counseling after personal or community disasters; and prevention of relapse in schizophrenia, bipolar disorder, or substance abuse with very early detection of prodromal symptoms and signs.
d. Tertiary: Reversing dementia due to vitamin B deficiency with appropriate vitamin supplementation illustrates tertiary prevention.
e. Quaternary: This is exemplified by the prevention of iatrogenic conditions such as antipsychotic-induced tardive dyskinesia, anticholinergic confusion, or delirium.

POSITIVE PSYCHOSOCIAL FACTORS

A key tenet of positive psychiatry is that positive outcomes such as those described above are at least partially mediated by and can be fostered by the enhancement of intrapersonal positive psychosocial traits as well as positive environmental/social factors, together subsumed under the rubric of PPSFs. Most of these factors are valued highly by society, yet until recently, they have been generally neglected in the biomedical sciences as imprecise, amorphous concepts that lack relevance to traditional medicine or neuroscience research. There have been numerous studies in recent years suggesting that the PPSFs are tightly linked to human biology and are associated with positive health outcomes.

POSITIVE PSYCHOSOCIAL CHARACTERISTICS

PPSFs may have as strong(if not stronger) an impact on patient well-being as common health risk factors such as obesity, hypertension, sedentary lifestyle, smoking, and even objective overall health status. The provision of effective interventions to strengthen PPSFs in older psychiatric patients could substantially increase the prevalence of recovery in seriously mentally ill older adults. Some of the key intrapersonal constructs (positive psychosocial traits) and positive environmental factors are considered below.

Positive Psychosocial Traits

Resilience. *Resilience* refers to ready recovery from or positive adaptation to illness, depression, or other adversities. Resilience is associated with greater well-being and reduced mortality risk among older adults. People in their 90s who endorse higher levels of resilience have a 43% higher likelihood of living up to 100 years compared to their peers with lower resilience. Among people with medical illnesses, resilience is also associated with better treatment adherence, better self-care behaviors, and improved quality of life. Among physically ill patients, resilience is associated with improved physical health, health-related quality of life, self-care, and treatment and exercise adherence. Resilience is also associated with better emotional health and well-being.

Optimism. The term *optimism* refers to a characteristic of people who tend to expect good outcomes. Optimism is associated with a lower risk of depression and higher overall subjective well-being, lower mortality, as well as less pain, better cardiovascular, oncologic, pregnancy, and other physical health outcomes, and better immune function. The precise mechanisms through which optimism has these effects are not fully clear, but it may partially operate through its effects on health behaviors. Older adults with higher optimism are more likely than less optimistic age-comparable peers to consistently engage in healthy behaviors.

Personal Mastery, Coping Self-Efficacy, and Meaning in Life. *Personal mastery* refers to an individual's expectations of her/his ability to achieve self-desired outcomes. A closely related concept is that of *coping self-efficacy*, that is, the individual's self-perceived ability to perform the requisite coping behaviors needed to overcome life challenges. Individuals high in personal mastery or coping self-efficacy have a belief in control over their life circumstances and future—that is, they have a general sense of control over things that happen to them and have greater confidence they can solve problems in their lives. In contrast, *optimism* more broadly denotes a tendency to expect positive outcomes regardless of whether or not one is the agent of those outcomes. In the context of chronic life stress, personal mastery and coping self-efficacy may promote specific, adaptive, goal-oriented behaviors, as well as maintenance of those behaviors, despite ongoing stresses. High levels of personal mastery tend to protect people from the potentially negative effects of stress on general health.

There is also growing evidence showing that *meaning or purpose in life* is associated with better mental and physical health. Developing a purpose leads to greater well-being and productivity.

Wisdom. *Wisdom* is a construct with heuristic value in that it appears across most cultures and contrasts with factual knowledge or even intelligence. Although traditionally, this construct was thought to be the province solely of philosophy and religion, recent successful efforts to develop standardized quantitative measures have also advanced the scientific study of wisdom. Wisdom may be defined as a complex trait with several domains, including prosocial attitudes and behaviors (compassion, empathy, and altruism), social decision making or problem solving, capacity for self-reflection and understanding/insight, decisiveness, acknowledgment and acceptance of uncertainty, emotional regulation, tolerance of divergent value systems, openness to new experience, spirituality, and a sense of humor. What unites these components is their utility for the self (e.g., greater well-being) and for others (better relationship with others and serving the common good). The cumulative experience of life with age may promote some of the dimensions associated with wisdom. Some, although not all, studies suggest an increase in several domains of wisdom with aging that may be important for an older adult’s ability to survive and even thrive in spite of worsening physical health. The Grandmother Hypothesis suggests that wisdom transmitted to younger generations may provide species fitness advantage and help neutralize the evolutionary pressure associated with loss of fertility in old age.

Recent research has also shown that wisdom has a strong inverse relationship with loneliness and may thereby protect against the deleterious effects of loneliness on medical morbidity and mortality. Although sometimes wisdom is contrasted with knowledge and “book learning,” there is emerging evidence that key components of wisdom, such as empathy, compassion, and self-compassion, may be enhanced with compassion training, mindfulness, and other contemplative interventions.

Spirituality and Religiosity. Religious and spiritual practices are reportedly associated with greater well-being as well as better health outcomes throughout the lifespan. It may be argued that *religiosity* is better conceptualized under the umbrella of positive environmental factors (see next section) as the term *religiosity* is usually reserved in reference to involvement in organized religion and thus has an inherent social connotation, whereas spirituality can be personalized. However, religiosity ultimately rests on the beliefs and behaviors/choices of an individual. The term *spirituality* refers to an internal experience, that is, the degree to which one's personal beliefs, thoughts, and behaviors focus on transcendent topics such as the meaning of life, belief in a higher being, power or level of consciousness, awareness, or existence. Religious and spiritual practices are associated with positive outcomes such as greater well-being as well as better health outcomes. These positive effects of religious practices may partially rest on the emotional support derived from the religious community. Religious and spiritual beliefs also tend to confer a sense of optimism. Spirituality has been reported to increase with age.

Positive Environmental Factors

In addition to intrapersonal positive psychological traits, the interaction of the person with the environment and the nature of that environment also impact the likelihood of positive outcomes. These environmental factors are described below.

Social Engagement and Support. *Social Engagement* refers to integration into a social network or social participation—that is, how well-integrated one is into a social network. Within this construct are the number and quality of close relationships, the frequency of socialization, and the degree to which one finds meaning or pleasure from social integration/interactions. A related construct of *social support* refers to the degree to which other people are available for emotional and physical support. Empirical research has shown that the quantity and quality of one's social relationships are associated with better mental and physical health outcomes, including lower mortality, as well as more specific health outcomes such as lower prevalence of hypertension, cardiovascular disease, dementia, depression, anxiety, and substance use disorders in young and old adults.

Family Dynamics. A particularly influential form of social engagement and support is the family. There is a large amount of empirical literature showing that family dynamics and the degree of a supportive family environment affect mental and physical health, including symptom severity, treatment response, and recovery.

Other Environmental Factors. Access to quality physical and mental health care, as well as environmental factors such as availability of safe parks and walking paths, community centers, and access to grocery stores for healthy eating alternatives, can promote or discourage physical activity and exercise, nutrition, and stress reduction, especially in older adults.

BIOLOGY OF POSITIVE PSYCHIATRY

As noted above, psychiatry, as a branch of medicine, is rooted in biology, and so is positive psychiatry. Biology of relevant constructs includes neuroscience as well as genetics and epigenetics involving interactions among genes, environment, and structure and function of the brain. This type of research has implications for developing biologic interventions to enhance positive traits such as wisdom, resilience, and optimism, and thereby benefit mental and physical health. Work on biologic aspects of PFSFs has accelerated during the past decade, but there remains an obvious need for additional investigations in this arena.

Potential Biomarkers of Positive Mental Health

Allostatic load and telomere length are among putative biomarkers of stress and aging but can also be conceptualized as potential biomarkers of well-being in reverse.

Allostatic Load. Allostatic load reflects the body’s cumulative physiologic response to frequent and sustained exposure to environmental stressors; it represents dysregulation of one or more biologic systems, multiple pathways to disease, and the cumulative cost of antecedent challenges which together can serve as an indicator of morbidity, as well as affecting cognitive functioning and psychological factors. There is no single measure of allostatic load, but a commonly used composite includes systolic and diastolic blood pressure, body mass index, serum cholesterol (with an emphasis on HDL), and plasma norepinephrine and epinephrine.

Telomere Length. Telomere length is an indicator of biologic age and may represent a cumulative index of the number of cell divisions and a cumulative record of exposures to genotoxic and cytotoxic processes such as oxidation. Telomere length is maintained by the enzyme telomerase, and there is some preliminary evidence that healthy lifestyle changes, as well as psychosocial stress reduction interventions, can increase telomerase activity.

Oxidative Stress. Oxidative stress, caused by an over-production of free radicals or underproduction of anti-oxidant molecules, damages DNA, protein, lipids, and other macromolecules in many tissues, with the brain being particularly sensitive. Oxidative damage to cellular components by free radicals may be an important component of the aging process. Thus, prolonged or repeated exposure to oxidative stress may accelerate aspects of biologic aging, leading to greater comorbidity and mortality.

Inflammation and Immune Function. Neuroinflammation and immune function also relate to several PPSFs. For instance, a low level of optimism has been reportedly associated with increased inflammation markers. Reduced personal mastery resulting from chronic stress may provoke excessive activation of the autonomic nervous system, which may, in turn, affect immune functioning. Several studies report direct associations of engagement in pleasant events with better health, including reduced plasma concentrations of inflammatory biomarkers and lower catecholamine response to stress.

Genetics and Epigenetics. Genes clearly play a role in determining the lifespan and health status in older age. Many PPSFs are also influenced by genetic factors. For example, resilience and optimism are both partially heritable. Beginning in development, an individual's genes and their interactions with environmental factors may shape the neural circuitry and neurochemical function expressed in PPSFs. Various genetic polymorphisms affect a person's limbic reactivity and prefrontal-limbic connectivity. Adaptive functioning of fear, reward, emotional regulation, or social-behavior circuits underlies a resilient person's capacity to face stress. Stochastic epigenetic changes occurring during brain development that drive resilience and hardiness may affect response to periods of high stress.

About 20% to 30% of the variability in human lifespan appears to be attributable primarily to genetic factors. Overall, longevity seems to be promoted by an absence of genes that predispose people to diseases rather than by the presence of "life-extending" genes. The risk for cognitive impairment in older age is clearly raised by the presence of the ApoE4 allele, but this may be attenuated by higher educational attainment or greater "cognitive reserve." In short, genetic vulnerabilities may be amenable to modification through intentional or incidental environmental changes.

Neuroplasticity Across the Lifespan

Throughout most of the history of neurology, the prevailing assumption was to see childhood as the period of brain development and later life as a period of neurodegeneration. But the past two decades of neuroscience research have shown reality to be more complex as both processes, development, and degeneration, occur throughout the lifespan. For example, adolescence is a period of programmed pruning of neural synapses, yet new synapses and even neurons can form in certain subcortical regions in older adults who stay active physically, cognitively, and psychosocially.

There are now convincing empirical demonstrations that neuroplasticity, with associated brain growth and development, continues into old age. Mechanisms underlying neuroplasticity include compensation for aging-associated degenerative changes (e.g., involvement of larger numbers of neuronal networks in the performance of activity) as well as synaptogenesis, increase in the number of dendritic spines, and even neurogenesis in selected areas of the brain such as the hippocampal dentate gyrus and periventricular region. Such neuroplasticity is related less to the genes inherited than to the behavior, attitude, and environment that affect the expression of those genes. It is this neuroplasticity that may enable PPSFs to affect an individual's well-being throughout the lifespan, although the brain is admittedly less plastic in later life than it is in childhood and early adulthood.

INTERVENTIONS

Research on interventions aimed at promoting PPSFs is in the early stages but seems highly promising. Treatment trials have shown beneficial effects of behavioral strategies buttressing resilience, changing attitudes toward aging, or incorporating meditation on outcome measures such as well-being, as well as alcohol consumption, biologic response to stress, and mortality rates in older adults**.** There is considerable diversity in the types of psychosocial or behavioral interventions reported, which include writing gratitude letters, practicing optimistic thinking, acts of kindness, replaying positive experiences, socializing, life review, mindfulness, cognitive behavior therapy, life coaching, goal training, and forgiveness therapy. Cognitive behavior therapy has been shown to be effective in enhancing optimism and facilitating the reappraisal of traumatic events in a more positive light. Increasing optimism has been found to increase adherence to pharmacotherapy in formerly pessimistic individuals. Interventions aiming to improve social engagement, while not specifically targeting depression, appear to have antidepressant effects in older people. Studies of the longer-term effects of meditation have reported reduced mortality rates in older adults at risk for negative cardiovascular outcomes. A number of randomized controlled trials have shown the efficacy of psychosocial interventions to enhance components of wisdom such as empathy and compassion, emotional regulation, and spirituality.

Interventions to Enhance Healthy Aging

A key component of positive psychiatry in the context of working with older adults is the concept of successful or healthy aging. The quest for "antiaging" therapies and interventions has gone on for thousands of years, with as yet little in the way of a "cure" for aging being found. However, there are interventions that can delay the onset of disability and disease and prolong "healthspan." In contrast to earlier assumptions, many of these interventions, such as physical exercise, appear to produce benefits even among older adults.

Lifestyle Interventions. Lifestyle behaviors are a logical place to start when thinking about enhancing positive outcomes in older people. Physical exercise, proper nutrition, activity participation, and regular health screenings and vaccinations are among the most powerful and modifiable predictors of the health span. In addition to the positive effect of healthy behaviors on the cardiovascular system, recent research has provided compelling data that improvements in brain structure and functioning can be attained from improving lifestyle habits.

PHYSICAL ACTIVITY. The axiom “what’s good for the heart is good for the brain” has gained research support in recent years. There is strong evidence from randomized controlled clinical trials conducted among sedentary older people that increasing aerobic physical exercise can enhance performance on cognitive tests. Together, the empirical literature suggests that initiating exercise participation in later life may have significant effects that extend beyond physical outcomes and include cognitive and emotional improvements.

Using animal models and examining the biologic effects of exercise, it is likely that physical activity has multiple pathways leading to improvement in cognitive and emotional health. By reducing hypertension, the risk for cerebrovascular diseases decreases. By reducing obesity, stress on the skeletal system is diminished. Physical activity may also have the secondary benefit of increasing social engagement. Fall risk may be decreased by increasing muscle mass. Research from animal models suggests that at the cellular level, exercise may provide a mild stressor that may act as a kind of “inoculation” against other kinds of stress and may promote neuronal growth.

The Centers for Disease Control and Prevention suggests that adults engage in 3 to 5 days per week of moderate-intensity exercise (equivalent to brisk walking) for 30 minutes or more, stretching every day, and strength-building activities 2 to 3 days per week. Only about one-third of Americans meet the minimum exercise recommendations, and the prevalence of meeting these criteria decreases with age. At particular risk for not engaging in recommended levels of physical exercise are older people from ethnic minorities, who have lower educational attainment, or who have sub- or supernormal body mass indices.

A central challenge to increase exercise participation is identifying the barriers to exercise in routine life. The “walkability” of the built environment is an important consideration for enhancing engagement in physical activity, especially for older adults because they appear to prefer walking over other exercises.

DIET AND NUTRITION. Diet and nutrition are clearly related to health and other positive outcomes, and no other strategy for healthy aging has received as much research support as caloric restriction. Caloric restriction has been examined in worms (Caenorhabditis elegans), rodents, primates, and humans. Reducing caloric intake has been associated with increasing the lifespan of certain strains of mice and primates. In addition to extending the lifespan, deceleration in other aging phenotypes accompanies caloric restriction. The exact mechanism of caloric restriction is unclear, but it may involve reducing the rate of metabolism, perhaps limiting cellular wear and tear. Whether and how calorically restricted diets can be safe and palatable in humans remains to be seen; however, there are ongoing studies examining the impact of caloric restriction in older, overweight, or obese adults.

The content of dietary intake is also of interest to promote health, and in an epidemiologic study, a “low-risk” diet has been recommended one that includes a higher ratio of polyunsaturated to saturated fats, high in cereal fiber and marine fatty acids, low in glycemic load, minimal trans fats, and multivitamins. Additionally, moderate alcohol drinking (1 to 2 drinks per day), especially red wine, appeared to be better in the Nurses’ Health Study. As with exercise participation, only a minority of older adults conform to such a diet, and a growing proportion of people, including older people, are obese. Indeed, the rising incidence of obesity in the United States may significantly slow the rate at which life expectancy increases over the next 30 years–that is, obesity may decelerate the dramatic gains that have been made in life expectancy. Practitioners working with older adults need to provide dietary education, explaining the risks associated with unhealthy diets and encouraging healthier alternatives.

Biologic Treatments. The potential for biologic treatments in positive psychiatry is largely awaiting further research, but there does seem to be potential for advances in this arena. Recent research suggests that it might be possible to use neurobiologic approaches to enhance resilience in the context of anxiety and mood disorders. With an increased understanding of the neural circuitry underlying resilience, new interventions may also be developed using findings indicating that individuals can be trained to modulate their own brain activity with the help of real-time functional magnetic resonance imaging (fMRI)-based neurofeedback. Biologic interventions may be developed on the basis of an improved understanding of neuroplasticity as well as gene variations related to positive traits. In addition, findings from animal and human studies might eventually yield new pharmacologic agents that can maximize the adaptive function of the HPA axis as well as monoamine, neuropeptide, and other neurochemical stress response systems.

Public Psychiatry

56.1 Public and Community Psychiatry

Nidal Moukaddam, M.D., Ph.D., and Asim A. Shah, M.D.

"I am proposing a new approach to mental illness and to mental retardation. This approach is designed, in large measure, to use Federal resources to stimulate state, local, and private action. When carried out, reliance on the cold mercy of custodial isolation will be supplanted by the open warmth of community concern and capability. Emphasis on prevention, treatment, and rehabilitation will be substituted for desultory interest in confining patients in an institution to wither away."—John F. Kennedy, Message from the President of the United States Relative to Mental Illness and Mental Retardation, February 5, 1963.

WHAT IS COMMUNITY PSYCHIATRY?

Community psychiatry, historically, blossomed and evolved in parallel with the push for deinstitutionalization and closure of large psychiatric facilities in the 60s and 70s. The overarching vision included geographically centered coordinated care for the most vulnerable and severely ill members of society. The target population typically suffers from triple serious illness: psychiatric, medical, and addictive, and often has a history of traumatic life experiences, compounding the treatment complexity. Based in public sectors, community psychiatry has evolved to encompass a diffuse network of treatment locations and modalities that diverge from its original character. Since the passage of the 2010 Patient Protection and Affordable Care Act (ACA), the experience of public, social, and community psychiatry has been transforming, with multiple changes in behavioral health care delivery and conceptualization. The term public can refer to psychiatric programs, treatment, or institutions paid for by public funds or as objects of public policy, whether paid for or not. Traditionally, community, or public psychiatry contrasted with private psychiatry, the latter being the entrepreneurial practice of delivering services to individuals having some means of purchasing them. As discussed below, expansion in inclusion criteria of recipients of community psychiatry has led to changes in its theoretical and practical scopes.

Funding for public and community psychiatric services tends to be provided by federally legislated appropriations that are passed through state, county, and municipal government agencies (such as departments of mental health; substance use treatment services; children, youth, and family services; and public health, social services, education, adult corrections, and juvenile justice agencies). Ultimately, most public psychiatry and community services are provided by not-for-profit community mental health, substance use treatment, child guidance, social services, or health care organizations that either are funded by or subcontracted to government agencies. Thus, the very existence of public and community psychiatric services and the policies and resources determining how they are delivered are extremely dependent on legislative mandates and fiscal appropriations from all levels of public government.

Psychiatry practitioners and administrators working in the public sector must be knowledgeable and savvy concerning the laws, regulations, and funding mechanisms relevant to their services. There is recognition of the prevalence of substance use disorders, both as primary disorders (often in combination with mental disorders, that is, “co-occurring” substance use and psychiatric disorders) and as secondary disorders (when mental disorder[s] are the condition of the first onset of primary concern, i.e., “comorbid” psychiatric and substance use disorders), and community psychiatry clinical workflows must reflect the various layers needed for effective treatment.

THE ROOTS OF COMMUNITY PSYCHIATRY

The precursor for community psychiatry, described below, was termed *boarding out*. As early as 1864, Sir Arthur Mitchell, in his work titled “The Insane in Private Dwellings,” discussed how mental health care did not have to be limited to asylums and how this expansion did not necessarily have to relate to limited asylum bed capacity, but rather a true ability to provide proper community-based care. The term community, as historically applied to psychiatry, connotes the mental health status of a specific, geographically defined population in a specific geographical catchment area. It is synonymous in all respects with “not the state hospital” and is contrasted to institutional care, especially in the move to community mental health in the second half of the 20th century.

The concept of “boarding out” and living with family despite chronic mental illness was tested in Scotland in the late 1800s as well. A major survey of individuals with mental illness in 1862, based on 7,000 home visits, revealed that the number of people living in asylums was about equal to the ones outside asylums and that homelessness was a major issue, even at the time. The other trend that Mitchell described, even in 1862, was that individuals with mental illness suffered often precipitous socioeconomic decline, sometimes affecting their entire families. These discoveries were in parallel with epidemiologic mortality surveys of individuals with psychiatric illness in the community and with mortality surveys. They are also echoed in modern literature that gave rise to community psychiatry: one example is the thought that individuals with chronic psychotic disorders such as schizophrenia become less employable and end up in lower socioeconomic classes than peers of comparable age. The social drift hypothesis was re-explored using population, twin, and molecular genetic data, with the conclusion that the downward sociofunctional drift was largely due to genetic, not environmental influences, though the role of "social defeat" and trigger events preceding first psychotic episodes, has long garnered interest as a factor in desensitization of the mesolimbic dopamine system. Regardless of the reasons for this drift, the community psychiatrist often encounters complex patients with limited employment histories and limited social functioning, reflecting the impairments of negative and cognitive domains of schizophrenia.

The concept of chronic mental illness being compatible with a noninstitutional life rhythm was espoused by writers such as Susser, who outlined modern applications of the concepts in the 1960s and the experiment of community psychiatry in Salford, Britain. The goal was, and still is, to treat mental illness on an outpatient basis and, by providing psychosocial support as well as psychiatric care, to aim for full integration of individuals with severe mental illness (SMI) in society.

The term psychiatry originally described the medical specialty focused on the care of persons with mental illness in the state hospital setting. Its domain was strengthened by the dominant role of the medical superintendents of the state hospitals (who would eventually be called "psychiatrists") and their medical colleagues in the latter half of the 19th century and the first half of the 20th century. However, in the era of community mental health in the latter half of the 20th century, the term exploded to cover a host of disciplines, and new personnel was recruited to staff the community-based supportive treatment systems that were supposed to take the place of the institutions. Nursing, social work, clinical psychology, various therapeutic specialties, and non-degreed direct care providers all became labeled as part of psychiatry. One of the most dramatic changes emerging since the late 1990s is the role of consumers of psychiatric services as providers in their own right through networks of peer-support services and advocacy initiatives. Family members of people with these disorders are also increasingly taking a more assertive role in treatment and support.

Different phases are noted in how mental illness was viewed in the United States: Colonial times and the early years of the Republic were the era of the poorhouse, during which the great majority of persons with mental illness found refuge or were confined for their own and others' protection as part of local community management. Care and custody were the operative functions, and treatment was nonexistent. In the 18th century, the ideals of the Enlightenment formed the basis for a paradigm shift toward fostering a better life for persons with mental illness rather than condemning and isolating them, ushering in an era of “moral treatment” (aimed at restoring the capacity for ethical conduct) through a return to the pastoral rural environment of the preindustrial age (“the Retreat”). In the mid-19th century, the protection and moral rehabilitation of the mentally ill was scaled up and institutionalized through the pioneering work of Dorothea Dix, resulting in an age of the asylum, during which public inpatient facilities, generically called state hospitals in the United States, were constructed in every state. A century later, advances in medicine, psychodynamic psychiatry, biologic psychiatry, and cognitive-behavioral psychology, along with a remarkable policy consensus, moved federal legislation to shift from institutionally based care to an era of community mental health. Finally, as health care costs began to soar at the end of the 20th century, and as employer purchasers and government moved to create market-driven health care, mental health policy moved conceptually to tightly organized systems of care that focused on prevention, early intervention, and intensive community care for children with severe emotional disturbances and their families and community support and recovery for adults with serious, acute, and persistent mental illnesses. The policy and concept, although ideal, remain partially operational with the smooth provision of care constantly jostled by bureaucratic, regulatory, and economic potholes.

In the American colonies and in the early days of the Republic, the care of the mentally ill was modeled on the practices of 18th-century England, where the Enclosure Laws disrupted the rural social order and set thousands on the road to seek shelter and employment in the cities. People with mental disabilities were at a particular disadvantage. They were saved from vagrancy by confinement in poorhouses, prisons, and jails, along with criminals, debtors, and other people with disabilities. In the American colonies, most towns would establish a poorhouse, and persons with mental illness, especially those who were found to be disruptive, would be committed by the actions of local government to extended stays in them. It is not that there were no hospitals. The construction of a public hospital was first proposed in Virginia in 1766. The money was appropriated in 1770, and the Public Hospital at Williamsburg opened in 1773, which was the first public mental hospital in the colonies. In Massachusetts, McLean Asylum opened in Charlestown in 1818. The first large state hospital opened in Worcester, Massachusetts, in 1833.

The physician superintendents of these early hospitals were the reformers of the era, following the ideas of moral management put forth by the French reformer Philippe Pinel. Pinel believed that if people were removed from their urban environments, relocated to an asylum in a beautiful pastoral setting, engaged in agriculture and the trades, lived in close proximity with staff, and were treated with kindness, then soon they would fully recover from the behavioral changes that they manifested as a result of having lived in a stressful, demanding environment. Benjamin Rush, a signer of the Declaration of Independence and considered the founder of American psychiatry, applied many of these theories and methods of his own in the treatment of the insane in the years after 1783 in the Philadelphia Hospital.

The great majority of those who experienced mental illness, however, were kept in poorhouses or jails under deplorable conditions and became a cause for reform. The Unitarian reformer, Dorothea Dix, had begun a 2-year survey of the conditions in which these people lived. In 1843, she compiled her findings in a Memorial to the Legislature of Massachusetts: “I tell what I have seen, to present the state of the insane persons confined within the Commonwealth in cages, closets, cellars, stalls, pens! Chained, naked, beaten with rods, and lashed into obedience!”

After the Massachusetts Legislature appropriated funds for a substantial expansion of the Worcester Hospital between 1844 and 1854, Dix traveled more than 30,000 miles, visiting hundreds of prisons, almshouses, jails, and hospitals, collecting data, and arousing public opinion to her cause. In 1848, with the example of federal support given to education, she sought federal support for national hospitals. President Franklin Pierce, who stated, “I cannot find any authority in the Constitution that makes the Federal Government the great almoner of public charity throughout the United States,” and vetoed the bill for federal support. Public mental health was, for the next century, exclusively in the hands of the states and the state hospitals that continued to be built only to be quickly filled and become hopelessly overcrowded.

Early American Psychiatry and Ties to the Community

It has been said that U.S. medicine reached a critical juncture toward the beginning of the 20th century. Science and medicine had established a strong alliance in the major university medical schools, and the profession had established powerful public credibility as breakthroughs transformed the practice of medicine. This has started the era of evidence-based practice. Psychiatrists were not at the forefront of this transformation, but they were profoundly affected by it. One of the most prominent psychiatrists of the period, was Adolf Meyer, and his life and career may be thought of as representative of what was happening to psychiatry. Meyer was born in Switzerland in 1866 and was trained as a neurologist. He came to the United States in 1892 and worked for 8 years in state hospitals in Illinois and Massachusetts. In this sense, he came from the ranks of the asylum psychiatrists who were the bulwark of the state hospital system that had, by that point, spread throughout the country.

The first public psychiatrists were state hospital superintendents, responsible for all institutional clinical and administrative functions. Within a few short years, the populations of state hospitals grew so that their treatment function was eclipsed by care and custody concerns. The superintendent became more of a manager and administrator than a treatment provider. The ability to organize and to bring order to the institution became a necessary skill.

The New York State Hospital system had established, in 1895, the Pathological Institute, which had two mandates: the study of mental diseases from the standpoint of cellular biology and the offer of instruction in brain pathology to state hospital physicians. The Institute sought to become the cutting edge of reform—not without opposition from the asylum psychiatrists, who were more oriented toward managerial and administrative concerns and clear demarcation of the diseased state of institutional inmates from the normality of functioning people in the community. Meyer became its director in 1901. When Henry Phipps endowed a psychiatric clinic at Johns Hopkins, Meyer was chosen as its first head. From Johns Hopkins, he played a leading role in American psychiatry for more than three decades.

Twentieth Century U.S.

At the beginning of the 20th century, the concept of dynamic psychiatry opened the possibility of psychiatry practiced in the community. Dynamic psychiatry blurred the distinction between health and disease and saw mental illness on a continuum. This allowed the center of attention for psychiatric practice to move beyond the institutions and to include troubled individuals in the early stages of illness. This approach elevated the significance of the life history and prior experience of each person. It was a short leap of faith to suggest that early community treatment might prevent the onset of SMIs that, up to then, had required institutionalization. The once strong bond between the asylum and psychiatry was unraveling. Dynamic psychiatry expanded the jurisdictional boundaries to include psychologically troubled individuals, as well as allegedly dysfunctional social structures and relationships. From 1880 to 1940, psychiatrists identified new careers outside of institutions. Psychiatrists articulated novel and sometimes bizarre theories and therapies; expanded jurisdictional boundaries to include not only mental disorders but also the problems of everyday life; proposed solutions for society’s ills; and defined a preventive role. In retrospect, it was an over-reach that subsequently led to questions about the credibility of the field and its foundations. What had been hypotheses initially were interpreted by some as factual and often damaging (e.g., the so-called “schizophrenogenic mother,” asthma as “a cry for help,” etc.). It was also during this “pre-chlorpromazine era” that psychiatry alienated itself from the rest of medicine. Despite its good intentions, it was, in retrospect, gross overstatement based more on conjecture and opinion than a scientific basis.

Meyer was a leading figure in advocating “a fresh and courageous pragmatism” and held “a biological conception” of human beings: “We must…accept the statement that all mental activity must have its physiological side and its anatomical substratum.” He developed a genetic-dynamic or developmental approach to mental illness, which he named psychobiology. He stressed the interaction of the organism with its environment and defined mental disorders in behavioral terms, tracing their origins to defective habits. He recognized the importance of consumer advocacy and supported Clifford Beers, a former mental patient, who wrote a celebrated work, A Mind That Found Itself, and who founded the Mental Hygiene movement.

Meyer was an empiricist, urging his colleagues to assemble and catalog facts. He was not a theoretician or a systematizer. Perhaps he realized that biology did not yet have the scientific tools to construct adequate theories about human mental processes. In this regard, he did not favor Sigmund Freud and what he viewed as the tendencies to dogmatic pronouncement. The eminent social historian of American mental health policy, Gerald Grob, observed that "psychoanalytic concepts…had far greater influence on culture and thought than on medicine in general or psychiatry in particular." This seems to overstate the case, given the great enthusiasm for psychoanalysis that came after World War II and that dominated popular perceptions of psychiatry.

On the eve of World War II, as Meyer retired, public psychiatry had advanced on three fronts. First, research institutes and psychopathic hospitals were developed alongside the state asylums in which research and training would benefit the care of persons with mental illness. These hospitals and institutes had limited success in that their research efforts to establish the efficacy of psychodynamic treatment progressed slowly, and they suffered a degree of mission drift away from the seriously and persistently mentally ill in the asylums and toward less severe mental health problems in the community. Second, an active consumer advocacy movement began in the founding of the National Committee for Mental Hygiene in 1909, which developed into a national movement focusing first on the plight of individuals in the asylums and then on mental health issues in the community. Finally, the ideas of dynamic psychiatry made it possible to think of the various stages of mental illness and the possibility of the prevention, amelioration, and potentially even cure of mental disease.

The 1950s were a time of great therapeutic optimism. Biologic psychiatrists pointed to the efficacy of drug therapy; their psychodynamic colleagues could point to psychological, psychosocial, and environmental therapies that would reach the most severely disabled institutionalized patients. Milieu therapy (the therapeutic community) arose in this period and had much in common with moral therapy. It appeared that medications were going to allow patients to engage in the therapeutic community, and then other innovations, such as unlocked wards and partial or day hospitals, were going to help some chronic patients transfer to the community.

As all of this momentum for change was building, a remarkable partnership for political action was developing among Robert Felix, the head of the newly formed National Institute for Mental Health, Senator Lister Hill, and Representative J. Percy Priest. Hearings were held aimed at focusing public attention on mental health problems and thus strengthening the case for an enhanced federal role. The Mental Health Study Act was passed in 1955, creating the Joint Commission on Mental Illness and Mental Health (JCMIMH). That Commission's final report, Action for Mental Health, did not make a clear-cut distinction between individuals with serious and persistent mental illness and psychologically troubled individuals. Although the JCMIMH report was a compromise among the 26 participating constituency organizations, nonetheless, there was strong support for fundamental change. Faith in the effectiveness of treatment in community programs was based on belief in the efficacy of early intervention, psychodynamic theories, epidemiologic efforts to elucidate the prevalence of mental illness in the community, and the putative identification of environmental variables.

At the end of the decade, with a new administration with an aggressive domestic agenda, the National Institute of Mental Health (NIMH) convened the Interagency Task Force on Mental Health, which developed the Blueprint for Action and, more importantly, activated the political coalition that made President Kennedy's initiative possible. The final policy sidestepped the provisions recommended by the JCMIMH for the refurbishment of the state hospitals and the provision of acute institutional care for the most severely disabled and devoted its attention to community mental health clinics, which it recommended to be enhanced to comprehensive community mental health treatment centers—the community mental health centers (CMHCs).

The national program for comprehensive CMHCs was in place. For the next 15 years, grants flowed to the localities and then through the states to the localities to the new centers, and states proceeded to build two community systems while beginning the process of phasing out the old state hospitals. The immediate discovery was that the CMHCs were able to expand mental health services for the communities but were not at all prepared to care for persons with serious and persistent mental illness who had spent most of their lives in state institutions. The discharge of 90% of the state hospital population (the deinstitutionalization process) without adequate community resources available was chaotic and often precipitous. It led to a class of homeless and generally untreated or transinstitutionalized individuals (put into nursing homes, prisons, squalid rooming houses, and hotels, etc.) who deteriorated outside the state hospitals. There also arose a peripatetic subpopulation with serious and persistent mental illness who often had comorbid substance abuse and generally avoided any beneficial involvement in treatment for a significant portion of the early phase of their illness. However, the states, to varying degrees, were set on a course of dismantling state hospitals that were becoming increasingly expensive. As federal staffing grants to the CMHCs were phased out and state contract dollars replaced them, the states gradually narrowed the focus of the community programs to its priority clients—the former residents of the state hospitals. Special programming models were developed to provide supportive programming for them that focused on community support and rehabilitative approaches rather than clinical ones.

As community mental health programs developed, it became clear that psychiatrists were, for the most part, playing limited roles: reimbursement could not support them full time, and they gravitated to private practice models that were appropriate for individuals with less severe mental health issues. The psychiatrists who were involved in the early CMHCs were quickly outnumbered by practitioners from the other disciplines and often sidelined themselves in private practice models in which they could treat educated and functional people with relatively mild disorders. One tongue-in-cheek publication during this era described the “YAVIS” individual as the “ideal” psychotherapy candidate…Young, Attractive, Verbal, Insightful, Successful. Many psychiatrists and others in behavioral health gravitated toward this profile for their ideal caseloads. These practice models limited their ability to treat persons with severe mental health disabilities without appropriate outreach and supportive care.

ORGANIZED SYSTEMS OF CARE

The psychiatric hospital is a special target of health care corporations. Its profit margins are large, investment costs are low, inpatient psychiatric care is now widely insured, and the complexity (and perhaps ambiguity) of psychiatric diagnosis and treatment makes cost control efforts by insurers and the government difficult. In 1968, for-profit hospital chains were nonexistent in psychiatric care. In 1980, investor chains owned 25% of private psychiatric hospitals, and, just 2 years later, these corporations owned a full 43% market share. Between 1982 and 1983, the number of investor-owned psychiatric hospitals rose 42.5%, from 106 to 151. The increase was partly attributable to investor groups’ acquisition of existing facilities, but the new construction of psychiatric hospitals, which grew 53.3%, accounted for most of the growth. “Ad-Psych” (Adolescent Psychiatry) units are so lucrative that corporations have closed units providing other types of services in order to establish the more profitable adolescent units. Admission data reflect the current domination of the private sector in the provision of adolescent inpatient psychiatric services. Lois A. Weithorn, in the Stanford Law Review, noted that in 1980, for example, private facilities admitted 61% of all adolescents who underwent psychiatric hospitalization; since that time, juvenile admissions to these facilities have increased substantially.

U.S. health care costs began to increase dramatically in the 1970s. By the end of the 1980s, they were spiraling. The article just cited by Lois Weithorn in the Stanford Law Review addressed the possible violation of children’s rights posed by their involuntary hospitalization in commercially operated psychiatric hospitals. It documented a trend of which U.S. employers—and the insurance companies that they hired to administer their health benefits—were all too aware. While employee health care costs overall were climbing, behavioral health expenditures were increasing by 50% each year. Venture capital had discovered a chink in the armor of health care finance. Even though there were lifetime limits for mental health benefits, a substantial amount of money lay in those coffers. Psychiatric hospitals were relatively cheap to build and could be designed to be converted to older adult housing facilities once the gap was closed. The criteria for mental illness were sufficiently permeable, and standards of care were sufficiently undefined that decisions for hospitalizations were made on behalf of many patients when more considered judgments would have found other alternatives. In fact, many hospitals launched deliberate marketing campaigns to fill their beds, and many practitioners participated. The trend was an abuse. Its most cynical aspect was that benefit dollars that could have been devoted to the care of persons with SMI were quickly extracted—a $50,000 lifetime limit could be spent in 60 days of private hospital care—so that sick patients were discharged to the care of public sector agencies.

Although several examples of health maintenance organizations (HMOs) had demonstrated their effectiveness in improving the health status of enrolled populations for several decades, U.S. employers were reluctant to require their employees to sign up for a plan instead of the traditional indemnity (or fee-for-service) health insurance. However, the growth of behavioral health expenditures was so dramatic that they overcame their reluctance for this sector. Within a few years, an industry of managed behavioral health organizations was created by the contracting activities of human resources executives of the major U.S. corporations. The new companies were staffed by a corps of seasoned mental health professionals, most of whom had been prepared in the ranks of the community mental health movement. They introduced, in a business-like fashion, utilization review techniques reinforced by elaborate information and communication technology. They selected panels of providers who could be trusted to care for enrolled members without inappropriate or extended use of hospital or other expensive care. Their impact was dramatic: Within a few years, behavioral health expenditures stabilized, at least temporarily.

The success of the carve-out of behavioral health care inspired employers to apply their contracting techniques to the rest of health care. Even though in 1987, only 27% were in managed care, by 1995, 73% of insured employees were enrolled in some form of managed care. Simultaneously, in the early 1990s, President Bill Clinton undertook a health care reform that attempted to provide universal health care as a highly regulated public entitlement. The Clinton health plan was labeled “managed competition” as a nod to the rapid move to competitive health care markets. However, the originators of that term—an assembly of business and health care experts known as the Jackson Hole Group—were much clearer about an approach in which government and government regulation would play a minimal role.

Nonetheless, a health care marketplace was created in the course of the failed Clinton health care reform. A wide variety of health care entrepreneurs would organize providers to bring their products to the markets, and consumers were encouraged to make choices that would ensure the value of the care that they would receive. The employers, through their contracting practices, sought to apply the principles of industrial organization to health care delivery to advance the ideal of organized systems of health care that were accountable and attractive to value-driven consumers. Although certainly, some excellent health care delivery systems have developed, most have fallen far short of these ideals in a full array of organizational structures. All of these structures and models fell under the term “managed care.”

In the early 1990s, managed care's utilization review techniques and benefits had restrained providers; HMOs and other plan types restructured health care delivery; the insurance industry transformed itself, acquiring HMOs and creating a new array of "products" for employers to purchase; risk was cascaded to hospitals, in many cases making them insurers and encouraging them to consolidate their positions in physician hospital organizations (PHOs); and physicians reorganized their practices into independent practice associations (IPAs) and multi- and single-specialty groups. By the mid-1990s, the rise of health care costs leveled off (temporarily), but there was widespread dissatisfaction among consumers and the rest of the system. By 2000, many of these measures were relaxed. Instead of benefits that restrained professionals, copays for consumers restrained their utilization. Employers encouraged broader networks, preferred provider organizations, and eliminated gatekeeper access to specialists. The insurance industry consolidated itself through cross-market mergers and large national contracts.

Quality and accountability began to dominate the health care market by the end of the 1990s, and consumers were encouraged to look to quality ratings by major accreditation organizations in making their choices. Managed care has had an indelible impact on the U.S. health care system, introducing issues of quality and accountability, reinforced by the Institute of Medicine's report Crossing the Quality Chasm.

How Community Psychiatry Became Its Current Self

As the process of deinstitutionalization proceeded and patients were moved from state hospitals to care in community programs, the financing also moved from institutional budgets to the categorical budgets of the state mental health agencies to fund the community programs. As employers moved dramatically to managed care in the 1990s, however, state Medicaid agencies followed suit and contracted with the Behavioral Health Managed Care Organizations (BHMCOs) to manage their mental health benefit. States quickly realized that by moving mental health categorical dollars into their Medicaid program, they could leverage Federal Financial Participation (FFP) into their state's general fund. Almost all of the states shifted large portions of their mental health budgets for direct services into the Medicaid program—hence the substantial increases in mental health funding. However, these services ended up in the stewardship of Managed Behavioral Health Organizations (MBHOs), whose products tended to be modeled on private-sector mental health care for general populations. Currently, patients are diffuse in communities, with the fragmentation of U.S. social welfare programs that is reflected in disparate payment systems.

Three contemporary trends have influenced the conceptualization of public and community psychiatry in the daunting climate facing U.S. health care. The first is the realization that the effect and pervasiveness of psychiatric disorders impose a global burden on society. The second trend has been the shift in funding for public psychiatric services from state expenditures, tied to the historic funding for state hospitals, to Medicaid, a health insurance model driven by the “medical necessity” for intervention. Finally, the power of reform efforts in general medical care and psychiatry have led to increasing demand for the use of evidence-based interventions defining quality, safety standards, and efficiency in the delivery of health care.

The first trend—the recognition of the burden of these disorders—can be most directly linked to a landmark study called the Global Burden of Disease. This study, funded by the World Health Organization (WHO), the World Bank, and several foundations, considered the leading causes of disability and premature death worldwide as a result of various health and situational problems. Of the ten leading causes of disability worldwide, five are neuropsychiatric, with the leading cause of disability being depression. When considering the leading causes of healthy years of life lost using the concept of disability-adjusted life years (DALYs), which reflects premature death and disability, depression was found to be in the top 3 in the world and in the United States. Mental health disorders were the fourth most costly health problem in the United States in 2000, 2004, and have only gotten worse in recent years. Schizophrenia, though not a highly prevalent disease, afflicts a substantial burden. When the cost to society of trauma-related disorders (which include post-traumatic stress disorder [PTSD]) are added in—and exposure to traumatic stressors has been found to play a role in both causing and moreover severely worsening most psychiatric disorders—the cost to the United States is ~50% more than the annual cost of heart disease and almost double the annual cost of cancer. New WHO data indicate that rates of various mental illnesses are increased to 22.1% in areas with war conflict (depression, anxiety, PTSD, bipolar disorder, and schizophrenia).

Second, after a period of critical evaluation of U.S. medical practice, the IOM, in its 2001 report entitled Crossing the Quality Chasm: A New Health System for the 21st Century, brought much clarity. This is a call to American medicine to reform inadequate service delivery systems and to apply effective practices systematically. It documented the need for a fundamental overhaul of the entire U.S. health care system, addresses the problems caused by insufficient quality in the health care system, and offers a road map for creating a new health system. A key principle in enhancing the quality of health care services is that treatments and practices must have a clinical and scientific evidence base in order to justify their utilization and costs. The Quality Chasm report was a primary influence among a series of reports from the IOM and other authoritative agencies in the two decades that laid the foundations for the health reform that has been codified in the ACA (2010).

Third, ACA-related changes to financing brought about an avalanche of changes in community mental health provision. The role of Medicaid in shaping public services for people with mental illnesses is difficult to overstate. For state governments, the appeal was almost immediate. When the states assumed the onus of care for people with mental illnesses, largely through the mechanism of state institutions, 100% of those expenditures came from state budgets—competing with all of the other priorities facing state legislatures. Medicaid, which is a state-federal partnership, allows states to shift between 50% to 80% of their cost for covered services to the federal budget. More recent federal laws and regulations mandating parity in eligibility and reimbursement for mental health (compared to medical/physical health) have attempted to direct more services to more individuals with mental illnesses. The Triple Aim: Better Care, Better Health, Lower Costs, has been the goal all along. Better Care refers to evidence-based psychiatry, integrated with primary care, in the context of coherent health care delivery systems.

The developments leading up to the ACA, as well as the statute itself, have laid the groundwork for the agenda of improving health care for public and community psychiatry. This is to be accomplished by CMHCs applying for status as Community Health Centers, or Federally Qualifies Health Centers (FQHCs), as well as strengthening the behavioral health services in the existing FQHCs. Fidelity to research-validated practices in implementing treatment and replication as the therapeutic model is aimed for, with some funding funneled through the Patient-Centered Outcomes Research Institute (PCORI). The ACA included the concept of a “Primary Care Residency” program to be based in community-based practices as Teaching Health Centers, including the FQHCs and CMHCs. Psychiatry is included as a specialty in those programs.

THE RECIPIENTS OF COMMUNITY PSYCHIATRIC CARE

Federally Qualified Health Centers (FQHCs) deliver care to the underserved populations in the United States. According to the Health Resources and Services Administration (HRSA), the health center program has 255,000 full-time staff and serves nearly 29 million patients. The number of patients served has tripled since 2000. More than half of FQHC patients belong to racial and ethnic minority groups, and almost 90% live in poverty, according to HRSA data.

At its inception, community psychiatry aimed to help communities as a whole, but over the years, much operationalization of what qualifies for treatment in community settings has taken place. Initial selection criteria reflected the population that was admitted to institutions and seeking care. Subsequent cost-cutting measures and refinement of workflows and protocols led to many restrictions but also much heterogeneity. The basic definition of serious mental illness aims to include the most vulnerable populations. In the Unied States, the term ***serious mental illness*** (SMI) originated from the National Plan for the Chronically Mentally Ill, a product of the President’s Commission on Mental Health (1978). SMI typically involves symptom severity and functional disability. Attempts to refine the concept of SMI resulted in redefinition by Substance Abuse and Mental Health Services Administration, published in the ADAMHA Reorganization

Act, Public Law 102–321, 1992, but states are free to use modified definitions, and more than 20 of them have adopted their own definitions. SMI definitions vary in Europe as well. Those definitions shape the funding received by organizations delivering community psychiatry in various states. The only common element of all SMI definitions is a psychiatric diagnosis, but the nature of the psychiatric disorder, disability, and duration vary by location. Psychotic disorders appear inclusionary in reviewed criteria, with mood disorders (major depressive and bipolar disorders) being the second most common category included in SMI classifications. Personality disorders are deemed by many to meet disability and duration criteria for SMI but are not accepted as entry diagnoses in some localities. This heterogeneity could have significant impacts on the purity and consistency of psychiatric nosology used in communities. This may lead to erroneous or exaggerated diagnoses of psychotic disorders, mood disorders or omission of substance-induced disorders, neurocognitive disorders, and organic causes of mental illness.

Financial Thresholds

Financial threshold to define recipients of community psychiatry services have also been used. Over the past two decades, entry into community programs has been linked to dual criteria incorporating both diagnosis and financial status. Recipients of community services often do not meet criteria for Medicaid, but after the ACA-related Medicaid expansion, some were able to get coverage; thus, coverage for community psychiatry now includes a spectrum of funding from uninsured, 100% to 138% of poverty/ eligible for subsidized private coverage, and Medicaid-eligible. Medicaid-only enrollees can be categorized as foster care young adults (ages up through 21), very–low-income adult parents, low-income peripartum women, or Supplemental Security Income (SSI) recipients. Income below 138% of the federal poverty level, meeting SMI criteria, and uninsured status are often needed to benefit from indigent resources. *Thus, community psychiatry now serves a larger swath of the population than it did at its inception in the 1960s*. It now serves individuals with SMI, but also individuals one could think of as the “working poor.” This is the group of workers who purchase health insurance because they do not receive health benefits from their employer, earn too much to qualify for Medicaid, and do not qualify for Medicare. With this expansion, the kinds of services needed and the spectrum of issues encountered become more variable, not limited to SMI, and therefore need a careful reassessment of the face and identity of community psychiatry.

THE ROLE OF THE PSYCHIATRIST IN COMMUNITY PSYCHIATRY

The psychiatrist, in their role as the medical specialist, trained in the discipline of medical sciences, had a very narrow focus, exercising medical and legal authority to take defined actions on behalf of individual patients. In the community psychiatry paradigm, the public psychiatrist practices psychiatry in publicly funded services and carries out programs that are mandated by public policy, interfaces with other team members, and is the team leader in the care of the patient with mental illness. As a public and community psychiatrist, they are engaged with a specific geographically defined population using community programs for the care of individuals with mental illness in order to improve the health of the community as broadly defined.

Psychiatrists in the public sector should work within a team that includes professionals from several disciplines (e.g., psychology, social work, nursing, occupational therapy, rehabilitation or addiction counseling, social services, housing, and employment specialists) and non-degreed direct care workers (e.g., bachelor's degree–level counselors or case managers, high school graduate, indigenous outreach workers, peer-support specialists, and family advocates), each of whom brings unique skills and experience to address the varied needs of people with severe and persistent mental illnesses. The team, rather than any single individual, assumes responsibility for the ongoing care of each patient across the many levels of services and often for many years. Its success is based on effective communication and coordination. Communication and coordination should be explicitly focused on the individual's (i.e., patient's and/or family's) stated goals, as well as on the community resources available and the team's technical and logistical capacities. Maximizing the individual's motivation to participate actively and productively in a comprehensive treatment plan that is patient-centered and collaborative is essential.

Psychiatrists can play four primary roles in multidisciplinary psychiatric rehabilitation teams: (1) conducting psychiatric diagnostic and treatment evaluations with significant involvement from members of the team; (2) providing thoughtful pharmacotherapy; (3) coordinating care with physical medicine in order to promote both physical and mental health; and (4) serving as the team's medical director, mentor, sometimes clinical supervisor, peer, and colleague.

The psychiatrist is being called upon to play a special role as the project or program medical director—with the attendant responsibilities of monitoring the medical safety and well-being of all patients and establishing or supporting management and clinical procedures that support quality of care and a cohesive treatment team. As the team's clinical Mentor, or simply as a team member, the psychiatrist serves as a role model for compassionate and professional behavior in relation not only to patients but also to all other team members. Formal or informal leadership is especially important when psychiatry residents and medical students work on a team as a training experience. The team psychiatrist serves not only as a mentor and a role model for the core aspects of psychiatric practice but also should demonstrate the values and skills necessary to integrate psychiatry within the framework of psychosocial interventions that are multimodal, community-based, and longitudinal.

The connotation associated with public and community psychiatry has been synonymous with care for the poor and underprivileged, care for special populations normally not attended to by the private sector, overwhelmed systems, low reimbursement and inadequate resources, inferior and unresponsive care, and a final common pathway for individuals no longer able to afford private care. This is not for want of their providers' dedication: it is the paucity of the physicians' numbers and the general public neglect of this sector. The patients of public and community psychiatry as a group lack the most basic resources to sustain themselves (food, clothing, housing, financial support, social support, etc.), and they are arguably the group least likely to be able to advocate for themselves and to have the capacity to recover from this default position. The needs of the patients, the inadequacies of the delivery systems, the lack of an adequate workforce, and the lack of coverage make the sector of public and community psychiatry a poster child for the attention of the ACA reforms. It also makes the practice of community psychiatry both noble and challenging. The shift from a narrow focus on the treatment of a solo therapist to a broader psychiatric rehabilitation model, and now to models that stress the recovery of the individual, requires solid training (and continuing education) and hard work, as well as a combination of personal qualities, competencies, and expertise that have been summarized as "persistence, realistic optimism, a collaborative style, teaching ability, and networking and system coordination skills."

A major challenge to psychiatrists serving adults who have the dual burden of mental illness and socioeconomic disadvantage is the identification and enhancement of the psychological and sociocultural resources that can promote illness management and reintegration in a support system. The goal, of course, is recovery with the help of fully operational programs of assisting adults with severe and persistent mental illness to make the best possible adjustment in the least restrictive public and community settings.

THE INPATIENT TO OUTPATIENT AND COMMUNITY PSYCHIATRY CONTINUUM

Community psychiatry best exists in a system of care that attends to the full needs of persons with psychiatric illness. This need exists given the complexity and high frequency of co-occurring disorders in the patients typically served by community psychiatry teams. This would include inpatient care, emergency psychiatric services, substance use treatment modalities, social services, and functional rehabilitation support.

The ideal setup for treatment is that majority of treatment gets conducted on an outpatient basis, with flare-ups and crises being handled in transitional intensive programs and partial day hospitals, and for severe symptoms, in inpatient psychiatric units for short stays. Partial hospitalizations were found to be equivalent to inpatient care in meta-analysis. The advantage of preponderant outpatient treatment is both cost-driven but also mindful of the need to keep patients in their natural environment. An essential component for the success of community psychiatry is a linkage between various service components, so patients do not end up needing higher levels of care inappropriately. When patients are released, the cohesiveness of the conditions of release and careful considerations for re-entry in the community are essential to avoid re-hospitalization or treatment nonadherence. This area has had repeated formulas tried for the last two centuries, dating back to the state of Massachusetts in 1897. Economic drivers of decreased length of acute hospitalization overlay other factors that had driven community and social psychiatry to the forefront of psychiatry, namely optimistic beliefs that improved treatment options would lead to less need for acute care and that options for other conditions, such as addictive disorders, are available. Trends for treatment, however, show low usage of anticravings drugs and pharmacologic options for addictive disorders and poor treatment adherence to antipsychotics following hospitalizations.

The reality, however, is that there is a shortage of outpatient psychiatrists, a shortage of hospital beds, and many patients, up to 20%, awaiting hospitalization end up enduring emergency center boarding. Boarding affects patients with mental illness disproportionately compared to those with medical illnesses. Boarding is noted to be longer for patients with co-occurring illnesses, intellectual disabilities, aggression, and lack of insurance funding, all characteristics that tend to be more prevalent in community psychiatry samples. Once hospitalized, these patients have longer lengths of stays, and this is predicted by severity of illness, psychosis or bipolar disorder, polypharmacy, and need for emergency restraints/interventions.

The majority of caregivers for individuals with mental illness are family members, placing strain on communities. Care for a significant number of these individuals is poorly coordinated, and there is a recurring whorl of decompensation, emergency room visits, hospitalizations, various outpatient and sometimes residential programs, variable compliance and funding struggles with treatment, diagnostic confusion (e.g., schizophrenia vs. bipolar disorder, borderline personality vs. PTSD vs. depression, etc.), polypharmacy with lack of attention to guidelines or to metabolic consequences leading to the iatrogenic production of physical health problems for these individuals who then enter the cycle multiple times. Involvement with the judicial system is often part of the course. Thus, more recent focused attempts in community psychiatry have focused on jail diversion programs and better interface with the legal system. Additionally, within the legal system, there is a push to maintain treatment continuity and ensuring inmates receive psychiatric care consistently.

Case management remains a cornerstone of community psychiatry. The roles of the case manager include establishing rapport, coordinating with families, and connecting the patient to community resources. Some definitions of case management work are more holistic and focus on comprehensive care, with some models requiring case managers to work on social skills training and psychoeducation, for instance. The role of the case manager will also depend on the treatment model, with more intensive involvement, for instance, in ACT teams: in a comparison on ACT versus the standard care model, the intensity and frequency of visits varied, with 13 visits on average for the ACT team in the first 3 months, but 5 in the standard care model, and this difference reflects in the panel that a case manager can carry.

STIGMA AND DISCRIMINATION–AN OPPORTUNITY FOR COMMUNITY PSYCHIATRY

The Relationship Between Community Psychiatry and Health Maintenance

Community psychiatry has been evolving and adapting as psychiatry, as a discipline itself evolves. The worst-case scenario is the evolution of community and social psychiatry aspects to mere delivery of psychiatric services, with accompanying reductionism in diagnosis, treatment options, and views of mental illness. But this evolution also carries the potential to truly help our most vulnerable populations. The establishment of community psychiatry infrastructure and network can help further other needs of the population, including medical, substance use, and social. In that scope, community psychiatry, a branch of social psychiatry, can also serve as a springboard for wider wellness and theoretical, structural changes in health care by linking the social, psychological, and biologic spheres. In fact, with changes in managed care reimbursement and restrictions imposed by newer forms of health care, it is suggested that private psychiatry is starting to veer toward the models initially pioneered by community psychiatry. The historical separation of psychiatry from the rest of medicine, partly self-imposed and partly extruded by mainstream medicine, will hopefully be corrected as delivery systems change and as greater knowledge comes to influence more focused and effective interdisciplinary efforts.

The elements that make community psychiatry structures (in its more ideal form) a desirable model are: community psychiatry often involves teamwork with physicians, mid-level providers, nursing and case management, social work staff. These teams often interact with the legal system and families and (again, in ideal circumstances) with the patients’ medical teams. Additionally, community psychiatry often interacts with and serves racial and ethnic minorities. This offers the multidisciplinary interactions our patients need. It is intuitive to match wellness initiatives, educational initiatives, and medical monitoring and social services measures to existing multidisciplinary infrastructures. HRSA aims for coordinated, comprehensive, and patient-centered care, integrating medical, dental, behavioral health, substance use disorder, and patient services. Individuals with SMI (schizophrenia, bipolar disorder, major depressive disorder) are at increased risk of cardiovascular disease-related death versus controls, as evidenced by a meta-analysis of 92 studies totaling more than 1 million individuals. Risk factors for mortality include antipsychotic use, elevated body mass index. Additionally, other types of diseases such as infectious, endocrine/nutritional/ metabolic, circulatory, respiratory were elevated in all SMI categories (including borderline personality disorder). Excess mortality from cancer is present in SMI as well. It is estimated that individuals with SMI die 8 to 10 years earlier than age-matched cohorts, often from natural causes. Therefore, it is essential that care systems combine as many interventions and preventive services as possible in order to truly help patients who often lack self-efficacy to mitigate their own problems. Integrative care, combining medical, social, and psychiatric, and improving treatment adherence to antidepressant and antipsychotic regimens may have some protective effect on premature mortality.

An example of the interface of medical and psychiatric management in the goal of comprehensive care for patients is the Delivery System Reform Incentive Payment (DSRIP).

DSRIP represents system transformation aiming to improve clinical management across settings, aiming for larger-scale population health improvement and, ultimately, reduction in avoidable hospital use. In Texas, DSRIP was designed as part of Medicaid waiver, §1115 of the Social Security Act. Nested in the 2011 Texas Healthcare Transformation Quality Improvement Program, DSRIP measures were spread and planned through regional health care partnerships (RHPs). It targets Medicaid enrollees and low-income uninsured individuals and includes regional assessments, goals/rationale for projects/expected results/annual milestones, and metrics. DSRIP aims to transform care delivery by integrating systems of care, delivering high-quality care that meets guidelines, and ensuring patients get prevention and primary care services. An obstacle to this, of course, is access, so one of the aims is to increase patient access, provide patients with a positive health care experience, and offer timely, proactive, coordinated medical home care.

DSRIP applies to mental health, which has a high chronic disease burden and extensive need for care navigation upon hospital discharge. This leads to unmet mental and behavioral health needs, which often get compounded by health care provider shortage and access to care. Some of the DSRIP mandates include follow-Up after Hospitalization for Mental Illness (FUH) within 7, then 30 days, and initiation of Alcohol and Other Drug Dependence Treatment on a continuum with hospitalization. Health systems have a choice in what measure to implement for their populations as well within the DSRIP context. The example of the Harris Health System in Harris County, Texas (the third largest county in the United States) was an alignment of elements needed for physical care and to meet guidelines for antipsychotic prescribing. The measures chosen were HbA1C and physical exams. Periodic reminders were built in the electronic health records. A second-level intervention was to add lipid profiles and a patient health questionnaire (PHQ-9) added.

Other opportunities for care alignment include using home visits by case management to screen for unfavorable social determinants of health, domestic and intimate partner violence, and other issues. A poorly explored area in community psychiatry and its nexus with medical care is the provision of end-of-life care. SMI patients have limited engagement in end-of-life planning and endure much suffering, often with concomitant physical and mental clinical decompensation. A potential role of community mental health and accompanying social services would be to promote advance directives and prepare patients for potential medical issues which they are not receptive to when they are ill.

From a broader perspective, psychiatry embedding in community centers can also be useful for prevention. Prevention is a natural impulse for any public health model. A disease or debilitating condition that can be avoided through early intervention and timely treatment can save a neighborhood or community and secure the overall health of the population. Health plans and community care systems should adopt carefully designed benefit packages for their enrollees, and that include preventive services and early interventions. The major public payers, Medicare and Medicaid, have incentive-based funding mechanisms encouraging some accountability for the most medically vulnerable patients. Smart public and community psychiatry will position itself in accountable clinical entities that are actively engaged in early intervention and intensive, individualized care management.

Application of the traditional public health concepts of primary, secondary, and tertiary prevention has been lacking in psychiatry but is highly possible. Primary prevention involves addressing the root causes of illness with healthy individuals, with the goal of preventing illness before it occurs. Secondary prevention involves the early identification and early treatment of individuals with acute or subclinical disorders or high-risk persons to reduce morbidity. Tertiary prevention attempts to reduce the effects of a disorder on an individual through rehabilitation and chronic illness care management.

Universal interventions are those intended for the general public, such as immunizations or media campaigns providing information about illnesses, early warning signs, and resources for health promotion and timely treatment. Selective interventions focus on individuals at higher-than-average risk (e.g., persons with prodromal symptoms or a family history of psychiatric disorders) to reduce morbidity by enhancing resilience and preventing the onset of illness. Indicated interventions target individuals who are experiencing impairment as a result of illness as early as possible in the course of the illness to reduce the burden of the illness on the individual, family, community, and treatment system.

Psychiatric disorders most often follow a course over time that begins with an often lengthy period in which prodromal or subthreshold symptoms or functional problems precede the full onset of an impairing disorder. Psychiatry integrated into primary care is in a position to identify these early symptoms and intervene effectively. In primary care, surveillance for very early universal intervention is possible, and selective interventions can be easily made as symptoms are recognized. Intensive psychiatric services can be organized in the form of indicated interventions when disabling symptoms appear to establish a path to recovery. A good example is early detection for individuals at high risk for psychosis and providing early interventions to prevent conversion to first break psychosis.

A public health-oriented strategy for disease and disability prevention will involve early identification and intervention in cooperation with consumers, families, health care professionals, and educators. Psychiatric professionals can play a key role by bringing their expertise to the development of appropriate screening, assessment, education, and treatment strategies that, if implemented on a wide scale, may reduce the burden of mental health disability and facilitate recovery. Psychiatrists also can become involved in the social marketing of prevention services and programs to add expertise and credibility to support legislation, regulations, and commercial investment that will provide the economic base necessary for broad-based prevention programs.

Prevention interventions have been found to be effective with adults with a variety of risk factors or preclinical problems. For example, women who have been raped are less likely to develop PTSD if they receive a five-session cognitive-behavioral treatment than if their recovery is left to chance. Men and women identified with subthreshold symptoms of depression in primary care settings are more likely to remain free from the full syndrome of depression or, if they do become clinically depressed, they will be able to recover rapidly with treatment if their standard medical treatment is enhanced by education about depression and learning skills for coping actively with depressive symptoms or stressors. This includes women who are at risk for postpartum depression, who have been shown to benefit from in-home cognitive behavior therapy in the first year after giving birth. Children who show early signs of severe behavioral problems (e.g., aggression, impulsivity, stealing) have been found to be less likely to become severely and chronically behaviorally impaired and antisocial when they and their caregiver(s) participate in therapeutic programs designed to enable the child and caregiver to deploy executive functions (i.e., anticipating consequences, inhibiting reactive behaviors, problem-solving) while simultaneously strengthening their attachment bond with each other.

The Medicaid program includes a mandated program for Early Periodic Screening Diagnosis and Treatment (EPSDT) that broadly covers very early intervention and extends services through the 21st year. States have been slow to meaningfully implement the periodic screenings and full use of the program because of the potential financial liability of the program to the states. Consent decrees have, in some cases, been used to expand these services for children with severe emotional disturbances. EPSDT could provide a complete framework for the early identification of young children with psychiatric risk factors and would support the effective targeting of comprehensive mental health and parenting services in the primary care setting of the family's "medical home."

COMMUNITY PSYCHIATRY AND THE PUBLIC SECTOR

Psychiatry's relationship to public sector agencies has, with some specific exceptions, been one of detachment because of the dominance of the private practice models before the advent of managed care and also largely because of the nature and structure of U.S. social welfare programs. Many psychiatry training programs lack meaningful rotations in public sector settings. In contrast to most industrialized nations in which comprehensive social welfare reforms were integrated, U.S. social welfare programs grew incrementally and categorically, that is, one category of service at a time. Large-scale initiatives, such as President Johnson's War on Poverty, have been implemented in a piecemeal fashion by fragmented federal, state, and local government bureaucracies. Various social service agencies have been created through a process and set of alliances that has been called the iron triangle. Advocates form an organization to champion a particular cause, such as blindness, developmental disabilities, primary care, or mental health, among others. They find key legislative sponsors who advance the cause through legislation and appropriation. This creates a bureaucracy, and then bureaucrats join the alliance. Through successive legislative sessions, the alliance of advocates, lawmakers, and bureaucrats builds a stronger categorical agency; for example, adults and families with dependent children or people with biologically based, SMI. From the 1930s through the end of the 20th century, U.S. social welfare agencies were created on this pattern: The system has resulted in generous funding and hopeless fragmentation of effort at local service delivery levels in which each agency depends on separate funding silos that also deliver conflicting rules and regulations.

It has been said that "mental health is not a place." Psychiatrists have a role at the receiving end of every categorical silo because the clients of each categorical agency experience mental illness or various addictions. Services for children with severe emotional, mental, or behavioral disturbances are a dramatic case of the importance of psychiatrists taking a leadership role in promoting comprehensive rather than fragmented services. Five categorical agencies—child welfare, education, primary health, substance abuse, and juvenile justice—all have a responsibility to care for these children. Especially for the children with the most severe disabilities, protective services, special education, the juvenile probation officer, and the child's pediatrician all need the consultation and support of a skilled psychiatrist. The situation is similar for adults with SMI, for whom case managers, vocational rehabilitation counselors, basic needs benefits specialists, social workers, psychotherapists, substance abuse counselors, parole or probation officers, legal conservators, visiting nurses, peer specialists, and physicians all may be mandated to deliver services. The need for psychiatric leadership is equally important for those who care for persons with mental retardation or developmental disabilities, for the older adult, for persons in vocational rehabilitation programs, and for persons in correctional programs. Virtually all public resources come through this complex of categorical agencies.

Health policy is formulated between government and employer purchasers and expressed unevenly through public health functions in communities, consumers, and advocates. Academic psychiatry bears responsibility for research, training, education, and workforce development for a behavioral health system that is only loosely integrated into the health care system. It will be impossible to achieve the ideals of the public health perspective on public and community psychiatry unless ways are deliberately devised to engage committed and proficient psychiatrists in meaningful roles in the operations of these agencies. Again, the factors at play in health care reform provide an opportunity to integrate the efforts of the complex and fragmented array of health and social service agencies by an emphasis on the primacy of the clinical process (maintained within the PCMH), the revision of funding mechanisms to encourage clinical sponsorship by accountable clinical entities, and emphasis upon the implementation of evidence-based practice standards.

BARRIERS TO ACCESS

The National Comorbidity Survey replication reports that less than 40% of those with severe psychiatric disorders have had an encounter with a psychiatrist in the last year; that one in six (15%) has received minimally adequate care; that one in twenty persons with substance use disorders received care. Even when mental illness is identified, people with socioeconomic adversities often do not, or cannot, get adequate mental health services in their communities. For example, although it is estimated that more than a quarter of a million incarcerated adults in the United States have psychiatric disorders, few were detected or received treatment until they reached jail or prison. Federal and state correctional systems have instituted mental health screening and treatment programs to address psychiatric disorders as a health problem for incarcerated adults and to manage the problematic behavior that can occur in controlled settings as a result of mental illness. On returning to the community, the vast majority of prisoners with psychiatric disorders cease to receive more than minimal mental health services: A recent study found that fewer than one in six (16%—strikingly similar to the National Comorbidity Study finding) received steady mental health services, and only one in twenty with addictions received steady substance abuse recovery services. Thus, access to mental health and addiction treatment services is far better in prison than in the community. This obviously causes great concern because of the possibility that correctional facilities may be a de facto system of care for low-income people (often of minority backgrounds) with serious mental illness.

Evidence of serious and pervasive barriers to accessing mental health care can be found in several kinds of crisis situations. Children and adults in poverty increasingly are deferring physical and mental health care until illnesses become chronic and severe and then find it difficult to gain entry into any setting for services except public hospital emergency departments. Children with severe psychiatric or behavioral disorders are often held in emergency department facilities for days and even weeks because the staff cannot locate any treatment facilities with an appropriate level of care that have an opening or are willing to take the child as a patient (or to accept the child or family's insurance coverage or lack thereof). People who must rely on the public sector services thus face daunting obstacles when seeking appropriate mental health care because of the serious underfunding of practitioners and programs. The economic forces and public policy dilemmas that drive the ever-increasing cost of health care bear directly on public sector psychiatry, as well as on the lives of tens or hundreds of thousands of people who do not receive adequate care.

COMMUNITY PSYCHIATRY AND RECOVERY

It is important to survey where and how Public and Community Psychiatry will participate in the changes that are afoot for American health care and how it will pioneer and support recovery for vulnerable patients. The state hospitals were the first publicly funded health care, but they were separated in a strange way from the rest of health care as American medicine found its scientific legs in the reforms sparked by the Flexner Report in 1910. The strides that were made by medicine and science in the early 20th century were not possible for psychiatry because the tools were not yet available for the science of the brain. Psychiatry remained in the state hospitals with patients supported with public funds, and the separation between psychiatry and the rest of medicine widened. By the end of the century, this had changed dramatically, and psychiatry was building on a flourishing base of science. The change was advanced in the middle of the century when biologic psychiatry and the new medications began to be used and understood. But the hospitals were still operating, and the strange separation of psychiatry from the rest of medicine persisted. The former Commissioner of Mental Health in Massachusetts and Director of the NIMH's Joint Commission on Mental Health and Illness (1961), Jack Ewalt, MD, who had played a key role in the development of community mental health, wrote a small book that methodically detailed the operational decline of the state hospitals at the same time that the Hill-Burton legislation was funding sparkling new general hospitals in communities throughout the country.

The term Public and Community Psychiatry may change just as dramatically in the next decade as it serves more people and has access to newer medications but also the advantage of technology, wearables, and personalized medicine. The junction we are currently experiencing is that of aiming for remission or recovery.

ATTITUDES TOWARD COMMUNITY PSYCHIATRY

The premise of community psychiatry is to move care from institutions to the community. Thus, a direct correlate is to place clinics and other community resources in neighborhoods. An ideal scenario is full community acceptance and support of its most vulnerable individuals, but in fact, community psychiatry could face opposition from some neighborhoods; in this case, the opposition is linked to negative attitudes such as stigma toward mental illness, fear that community clinics would bring down the value of the neighborhood or bring about crime or violence, etc. Questionnaires such as the Community Attitude toward Mentally Ill questionnaire (CAMI) are designed to measure these attitudes and help guide public policy. Attitudes toward mental illness and community psychiatry can be viewed as individual versus societal. Different influences impact these two currents. Societal stigma links to systemic barriers, which are meant to be fought by community psychiatry establishments and systems. Individual stigma and discrimination are but one level of systemic stigma.

Overall, most people have neutral to positive attitudes to the idea of community psychiatry when it does not affect their lives unless they believe mental illness is associated with crime and violence. Increasing acceptability of community psychiatry would benefit from focused messaging and from starting mental services in a stepwise fashion. An important factor in increasing acceptability is also to increase individuals' direct contact with those who suffer from mental illnesses, as this step, increasing familiarity, has been found to help the acceptability of services.

As with other new concepts, the personality traits of recipients shape their responses on an individual level (for instance, using a big five-factor model, openness and agreeableness are associated with more acceptability and positive attitudes toward community psychiatry, whereas neuroticism is associated with less). Negative attitudes toward mental illness itself, such as believing that an individual with mental illness should be avoided and that marrying or partnering with someone with a mental illness is a bad decision (CAMI items), correlate with negative attitudes toward psychiatry, help-seeking, and community psychiatry perceptions. These opinions may be more negative in rural areas and in less industrialized countries.

Negative attitudes toward community psychiatry denote a poor understanding of the role and scope of the discipline. The advantage of having community services embedded in neighborhoods is to have accessible services bypassing access barriers and avoiding disconnecting the patient from their sources of support, typically families. Espousing negative attitudes to help-seeking and to community services easily leads to delay in care, presenting with more severe symptoms, and therefore reinforcing the view that mental illness is incompatible with normal everyday life. Of note, attitudinal barriers affect referral in mild to moderate cases, whereas structural barriers seem to be much more influential in severe cases, according to a WHO survey of 63,678 individuals with mental illness. As individuals with severe illness are the main recipients of community psychiatry services, it is essential that systemic and structural barriers be addressed, including societal ones.

A meta-analysis of studies on attitudes and perceptions toward mental illness shows an increasing trend toward better mental health literacy, moving toward a more biologic model of mental illness and perhaps greater acceptance of biologic, psychotropic treatments in middle- and high-income countries, but no significant change in stigma or attitudes toward mentally ill individuals.

Interventions to reduce stigma range from mental health education or provision of information, direct contact (shown to disconfirm stereotypes related to mental illness), indirect contact (increase familiarity), entertainment, and art (to replace stereotypes with healthier, more balanced views and more objective information), psychoeducation and even psychotherapy. In a review of more than 8,000 studies, Thornicroft et al. found that contact (direct) produces short- to medium-term knowledge improvement, but attitudinal improvement or does not occur. The impact of these attitudinal, stigma, and discrimination-based views can be far-reaching and affect funding and expansion of community resources, not just utilization. This area is not well researched and could benefit from manualization and increased fidelity in intervention delivery. Additionally, different campaigns could be needed for different types of mental illness and for low-, middle-, and high-income countries.

Attitudes of police officers are integral to community psychiatry response. For example, in an examination of how different agencies respond to borderline personality disorder patients, reviewers found that different agencies will assign different diagnoses to the same patient and hence deal with them differently, assigning them to different workflows. This illustrates the tremendous need to coordinate care frequently and across disciplines and institutions for successful community psychiatry outcomes.

Stigma and discrimination in community psychiatry also show in how police officers deal with mental illness, reflective societal prevailing attitudes. A common example is the use of restraints (handcuffs) when transporting patients from community settings to the emergency center or the hospital, even when the patient is voluntary.

COMMUNITY PSYCHIATRY AND PSYCHIATRIC TRAINING

According to the National Survey of Psychiatric Practice, more early and mid-career psychiatrists were working in the public sector/community psychiatry than in private settings, an increasing trend since the 1990s, with 2002 being the first year for more psychiatrists being in the former. In 1957, only 1,700 of the 10,000 American Psychiatric Association members worked in state hospitals. Within less than 20 years, the overwhelming majority of psychiatrists in the United States went from working in state hospitals to working in other settings that had little or no interface with the populations having an SMI or serious and persistent mental illness or with children with serious emotional disorders.

Training experiences in community psychiatry are required by the Accreditation Council for Graduate Medical Education. The swath of psychiatric care covered by community psychiatry has grown, and more psychiatrists practice in community-funded settings than in private practice or academic and research settings. Community psychiatry training tracks remain few and far between, with only four tracks being active in the United States in 2014. Creating alternatives to community psychiatry exposure in residency has relied on experiences with ACT teams or integrated psychiatry, though these two settings do not offer the same experience but rather some similarities. Community psychiatry fellowships focus on integrating care with shelters and primary care physicians to cover the spectrum of care the SMI population requires; the experience also focuses on building a human appreciation of the community psychiatry patient, an often traumatized individual dealt heavy blows by life. Despite all these limitations, there are views in favor of incorporating more community psychiatry experiences in psychiatry rotations, given the expansion of the field and the remarkable diversity of skills and collaboration opportunities it teaches.

What Skills Ought to Be Taught in Community Psychiatry Experiences?

The first is to improve knowledge of what to expect in the community psychiatry population, which has a particular profile of illness, as described in the SMI section. Patients in community clinics may often have complex trauma and overlapping symptoms, for which careful history taking is required. Familiarity with disease comorbidities is essential as most community psychiatry patients will suffer from co-occurring disorders. A common finding is that patients with psychotic symptoms of any nature will be labeled with a diagnosis of a primary psychotic disorder, such as schizophrenia or schizoaffective disorder, even when a proper diagnosis is a stressor or trauma-related disorder, or a substance-induced disorder. This label has implications for treatment recommendations and the adverse effect burden one may get from prolonged exposure to antipsychotics. Additionally, the stigma of having a psychotic disorder may cause detrimental long-term effects for self-image, hopes of recovery, and employment-seeking. More importantly, a mistaken diagnosis can lead to missed treatment opportunities, for example, focusing on pharmacologic measures and not referring to psychotherapy for trauma or giving antipsychotic medication but not an antidepressant.

The second skill essential to success in community psychiatry practice is efficient time management. As time is limited in most encounters, it is easy to skip elements of the interview that can be very revealing. Many learners are tempted to skip a formal mental status exam, recall testing, or to ask about first-rank psychotic symptoms, preferring to ask about hallucinations only. While time constraints are very real, the adequacy of history-taking remains the cornerstone of diagnostic delivery, and learning this skill is essential.

The adequacy of cognitive testing and of carefully surveying a prior history of violence and traumatic brain injuries has to also be emphasized. Individuals with SMI are at a higher likelihood to be victims of domestic and sexual violence, and individuals who have a family representative as a payee for their benefits (e.g., social security disability) are also noted to have a higher risk of family violence and victimization. Individuals who are homeless have a higher risk of traumatic brain injury compared to the general population. When rushing through a complex plan of care, often including off-label medication usage, the combination of head injuries, interpersonal violence, and untreated neuropsychiatric sequelae of these issues can largely contribute to poor understanding of instructions and poor follow-through. The same pattern can be found in patients with a history of heavy alcohol use. Thus, it is really important for learners to know how to complete thorough data gathering and select the types of cognitive tests, albeit brief, they will need to construct a proper formulation of the patient’s level of impairment.

Third, the essence of community psychiatry is an ability to absorb complex situations and histories and to work through them in teams. Learners need to practice interprofessional data gathering, sharing, and decision-making. The physician’s role in the community psychiatry team is pivotal but may be somewhat underemphasized. Learners will often find other team members thankful for a collaboration and for a nuances biopsychosocial formulation with proper use of terminology to accompany what they have already observed in their clinical interactions.

Fourth, the cultural aspects of community psychiatry, including engagement, understanding of the patients’ background, and respect of cultural beliefs, have to be taught. There may be, in some subpopulations, a high preponderance of issues such as war violence, a refugee experience, or human trafficking that learners may not be familiar with.

Last, the structure of busy clinics in community settings, away from academic support and supervision, takes adjustment and modification of workflow. It is not studied whether the rates of burnout differ for community versus noncommunity psychiatrists, but the volume and severity of psychopathology seen in community psychiatry necessitate healthy coping mechanisms and often involves introspective reflection on severe illness and social justice.

TELEPSYCHIATRY IN THE COMMUNITY

The advent of telepsychiatry has the potential to improve delivery to community psychiatry patients but also highlights disparities in internet access and the ability to benefit from virtual psychiatry experience. In community psychiatry, financial restrictions have made encounters with psychiatrists shorter than they had traditionally been. There has been a shift toward more biologic aspects of psychiatric treatments and a dissociation of therapy and medication management sessions. So the baseline, typical visit in a community psychiatry setting has been described as brief and focused. These changes have been consolidated since the managed care movement in the 1980s.

Adept community psychiatrists maximize the use of the limited time they spend with patients and maximize engagement in those encounters. Using virtual encounters, however, has been challenging for the patient population typically served in community psychiatry settings. To achieve a proper result in a physician–patient encounter, aspects of rapport-building, diagnosis, and treatment decisions must be maintained; and to do so, the level of immersion in the visit, the level of engagement/emotional distance, and privacy have to be managed. The physical elements of the encounter, referred to by the psychoanalyst and artist Milner as the “frame,” shift from in-person to virtual, playing the responsibility of privacy and adequate space to conduct the visit, and placing the onus of working out technical requirements and difficulty on the patient. Patients who do not have an adequate space to conduct the visit because of homelessness and lack of privacy in crowded living situations that many patients served in community psychiatry endure. This obstacle can translate into discomfort about discussing issues pertaining to the visit and potentially, because of increased sensory input, distractibility during the visit.

By and large, telepsychiatry is highly accepted, with some studies indicating that show rates in clinical settings improve with the use of virtual visits, as transportation barriers are bypassed and it is overall easier for patients. But it is not the case for individuals with SMI such as schizophrenia. Levels of engagement in therapy services and continuation of therapy use virtually may suffer as well in the SMI patient population. This fits with already known data from the Results From the National Comorbidity Survey Replication showing that by and large, individuals with significant mental illness remain under or untreated, especially in traditionally underserved groups, including older adult persons, racial–ethnic minorities, those with low incomes, those without insurance, and residents of rural areas, and therefore the patient populations that is the main target of community psychiatry. This is also the population hypothesized to not be able to fully utilize virtual visits. To engage in telepsychiatry, one has to have access to the platform needed and learn how to use the technology involved. The SMI population often has trouble with both, though once SMI patients are converted to telepsychiatry, they often remain and show equivalent levels of satisfaction to non-SMI patients. Thus, the difficulty may be to establish proper structural elements to help this transition. Of note, even though internet-enabled smartphone ownership is almost ubiquitous, patients with SMI in general, and psychosis in particular, hover around 78% in use, with even less owning a smartphone currently, and these parameters correlate with negative symptoms and cognitive functioning.

The Study to Promote Innovation in Rural Integrated Telepsychiatry (SPIRIT) study, currently underway in 12 FQHC in three states, aims to examine how to optimize engagement in care in patients with bipolar disorder or PTSD in a sequential, multiple assignments, randomized Trial design, and which of these patients would benefit from Telepsychiatry Collaborative Care. Preliminary data show that engagement in psychiatric care improved outcomes, but that success hinged on the presence of case management and psychology services in conjunction with telepsychiatry services; further, the telepsychiatry aspect is supplemented by an in-person case manager to facilitate adherence and implementation of treatment recommendations virtually given.

Virtual psychiatry applications for SMI can also clash with the nature of the disease targeted during the visit. The presence of delusions, such as mind-reading or persecutory delusions, belief of having an implanted chip or tracking device, could impair engagement with the psychiatrist on screen and potentially worsen the pre-existing delusion. Hallucinations would make engagement difficult as well and may be harder to redirect on screen compared to in-person interactions. Poorly controlled mood or personality symptoms, with acting out on screen (self-harm, using substances) is harder to mitigate virtually than in person as well. Potential negative outcomes of poor engagement could show as nonadherence with a treatment plan, dropping out of treatment altogether, and having to receive emergency or inpatient services because of clinical decompensation.

The addition of cultural and language barriers may further impair the successful use of telepsychiatry in non-English speaking patients. The Cultural and Linguistic Appropriate Services, via the U.S. Health and Human Services Department, outlines 15 standards of culturally competent care that have to be intermeshed with telepsychiatry structures and equipment and the ACGME framework. There are gaps in knowledge relating to applications of telepsychiatry to cultural aspects of community psychiatry. There are also severe gaps in determining the ideal clinical workflows to reliably help transitional the patients in community psychiatry clinics to virtual platforms successfully. It is likely that structural/organizational efforts have to be set in place for this purpose, including staff help to train patients on technology use, connect them prior to physician visits, and carefully review discharge instructions. These measures would help avoid further decreasing physician time and would solidify understanding of treatment recommendations. Special considerations should be paid to patients with substance use disorders needing regular drug testing, patients who receive long-acting injectable medications, and patients on medication regimens needing regular lab work monitoring.

ASSETS AND ADVANTAGES OF ONGOING PROGRAMS

The Harris County Experience

Houston, Texas, is the fourth largest city in the United States. Harris County, the third-largest county in the United States, has two networks of community psychiatry that work in a complementary fashion. One is a state-funded mental health system targeting the three main SMI categories (psychotic disorders, major depressive disorders, and bipolar disorders) and intellectual disabilities and strictly adhering to financial restrictions, thus serving the most vulnerable population in the county. Funded by the legislature, it follows all the above rules and provides an invaluable safety net to the community but providing outpatient services, a comprehensive psychiatric emergency program, and case management, and a crisis outreach service.

The second service, The Harris County Community Behavioral Health Program (CBHP), funded by the county itself, has had to grow and fill the gaps that state legislation does not cover. In doing so, an alternative model of providing community psychiatry services has evolved. In 2004, CBHP placed behavioral health staff, therapists and psychiatrists, into 21 community health centers in order to better meet the behavioral health and primary care needs of the uninsured county population, winning the 2007 American Psychiatric Association Achievement Award in the category of community-based programs. The program proved to be cost-effective, highly rated by specialists and primary care alike, and well-liked by patients who appreciated direct access to psychiatric services. As CBHP has continued to grow, options for specialized programs have emerged. Lessons from CBHP include the following:

- Direct access to psychiatrists works well for most patients, avoiding care delays and allowing quick treatment initiation and improvement.
- The absence of restrictions on diagnosis does not place a heavy burden on volume as initially feared. Past the first stabilization period, numbers have been manageable. Lack of diagnostic restrictions means that psychiatrists can do a proper diagnostic job and not feel compelled to add a diagnosis so the patient can qualify for services.
- Colocation with primary care and specialty medical services works well for patients who often have comorbid disorders. As discussed above, patients with SMI tend to be medically complex. Careful care coordination is often required for medication regimens, as antipsychotics while bringing benefits, may also worsen chronic medical issues.
- Substance use treatments are a must given the large percentage of patients who have SUD.
- Psychotherapy, both individual and group, are necessary for successful outcomes in community psychiatry given the high prevalence of traumatic experiences in this population.
- Culturally competent psychiatry is essential given the diverse makeup of our population.
- Colocation with other services offers opportunities to educate and provide informal support to colleagues, fostering collaborations.
- Multidisciplinary efforts allow better ability to screen for domestic violence, intimate partner violence, and human trafficking.

- Community psychiatry is very local in flavor. Every clinic has a particular population, certain diagnoses that predominate, or an ethnic or racial group. The microcosm of a clinic is often difficult to describe, but psychiatrists embedded in each one usually have a feel for the needs and characteristics of their specific subpopulations.

The positive growth of CBHP has paved the way for more specialty programs that have emerged to fill the needs of the community, based on careful gap analysis and a desire to truly and decisively improve the lives of our patients. Specialty programs include the follow.

Multi-Visit Patient Program (MVP)

As discussed above, the goal of a successful community psychiatry experience is the smooth transition of patients from inpatient acute hospitalizations when needed to outpatient care. This lofty goal is not always possible, and the literature is rife with descriptions of patients who often present to emergency services. These patients are often substance users but sometimes have psychosis, mood, or personality disorders. Derogatory terms such as frequent flyers were much used in the 1980s and were gradually replaced by more neutral terms such as MVP. The MVP program provides linkage of patients who have more than six emergency center visits per year to rehabilitation resources, housing resources, and other community resources as indicated. The main drivers of utilization seem to be divided into behavioral, social, and medical. Solving these issues is often not within the hands of the medical system or the psychiatrists, testifying to the interdependence of agencies on each other in the community psychiatry structure. The MVP program has been successful in mitigating recidivism for multiple individuals, much to the relief of staff and patients alike.

Maternal Perinatal Addiction Treatment Clinic

Based on the Maternal Opioid Misuse model (MOM) funded by Medicaid, the MPAT clinic aims to serve the needs of pregnant women with histories of drug use. Women who use drugs have a much higher chance of unanticipated pregnancy, shorter durations between pregnancies than recommended by the WHO for optimal health, and frequent negative outcomes in relation to domestic violence and intimate partner violence. Pregnant women will often try to stop drug use when they discover they are with a child, but often fail: women who are pregnant tend to use less compared to those who are not, use tends to decrease over the trimesters, but often quickly rebounds postpartum. They report feeling judged and embarrassed, not just because of substance use but also because of associated behaviors such as prostitution. The percentage of pregnant women who use illicit substances (drugs, alcohol, tobacco) is 20.8%, according to National Survey on Drug Use and Health, from SAMHSA. Beyond just numbers, substance use disorders have been gaining press as state after state (UT, CO) highlighted concerns about the significant contribution of SUD to maternal mortality. The Maternal Mortality and Morbidity Task Force and Department of State Health Services, in its 2018 Biennial report, recommends the following:

- ensure that women with substance use disorders and mental health conditions have insurance coverage for necessary care services;
- support models of maternal health care that integrate behavioral health services; and
- develop strategies to ensure that behavioral health and community services to support long-term disease management are readily available, including expanding the number of behavioral health care providers and services across the state.

Thus, there was clearly a need for a specific intervention. The group of women targeted for this intervention are frequently victims of the intersectionality of trauma, poor social determinants of health, risky practices, like substance use, and high-risk medical pregnancies, in addition to potential other medical conditions. The MPAT clinic provides multidisciplinary support from neonatology, anesthesia, addiction, and general psychiatry, psychology, social work, maternal–fetal medicine, and from social and community works in inpatient treatment centers. The program has linkage to substance treatment centers, the jail system, the child and family protective systems and is involved in outreach efforts. Since its inception, the program has seen a tremendous increase in the number of referrals, and has been able to implement Universal Substance Use Screening in all county clinics, as screening is found to be superior to urine drug testing, is not confounded by bias and false positives, and gives the opportunity to intervene during the screening. Substance use is likely underrecognized without screening, and the MPAT program is an example of an evidence-based, multidisciplinary intervention that is unique to community psychiatry.

THE LARGER PICTURE

Community psychiatry has the opportunity to shape perceptions of mental illness and fight stigma as its reach increases. By interacting with multidisciplinary teams and working on social determinants of health, it is possible to generate a positive, evidence-based picture of appropriate, successful treatments. To achieve success, community psychiatry has to tackle societal issues affecting its patients, including gun violence, homelessness, the role of the legal system, and the limitations of psychotropic medications. As discussed above, the groups of patients served by community psychiatrists no longer just represent the sickest individuals with SMI. Therefore, community psychiatry must become flexible and integrate treatment for co-occurring disorders and personality pathology. It also has to include health promotion and accommodate insurance system payments.

A little-discussed aspect of community psychiatry is the fact that it is the de facto safety net for chronic childhood disorders and intellectual disabilities but also deals with emergency center recidivism, inpatient hospitalization recidivism, etc. The next decade will see specific subspecialties burgeoning within community psychiatry. The examples of programs illustrated above give an idea of the growing scope of community psychiatry and the potential it has. Community psychiatry is not the same it was 10 years ago. Patients who are employed, but want ease of access and someone with the ability to handle difficult cases, may be the next community psychiatry beneficiary, and services will have to be flexible to accommodate those needs.

56.2 Reforming Health Care

NIDAL MOUKADDAM, M.D., PH.D., AND ASIM A. SHAH, M.D.

Reform is the process by which one achieves health and optimal utilization of health resources. Health care is provided in public versus private sectors, with the balance differencing by country and sociopolitical agenda of governing political parties. Yet the realities of care provisions are also heavily impacted by a country's financial resources and organizational capacities and broader geopolitical forces such as conflicts/wars and natural disasters. Thus, health care delivery, and therefore health reform, has to include a somewhat stable/static, long-term planning element and more dynamic adaptive capacity reflecting budgetary and sociopolitical realities.

Health care delivery occurs in acute, primary, secondary, tertiary, and community-based services. When thinking of reform, different strategies and goals apply to each setting, with the overarching goal of maintaining an efficient, nimble, and cost-effective health care continuum.

In the United States, the goals of reforming health care are

- improving the experience of care
- improving the health of populations
- reducing per capita costs of health care.

Another way to consider reform is to think of it as

- insurance market reform
- delivery reform
- payment reform.

One would also be remiss not to mention that the pandemic will have long-lasting impacts on reimbursement and medical models. A central theme of reform, to be conducted successfully, is to maintain the balance between innovation and collaboration and stability. Reform is inextricably linked to politics.

The COVID-19 pandemic has shown the perils of systems where health care coverage is not easily accessible and the financial needs of keeping a population healthy. This chapter will discuss how reform can gain from discrete, well-defined measures and how those measures interface with politics and the law. The interface of medical reform with legal issues can impact the environment in which physicians practice, via tort reform and change caps on economic and noneconomic damages, with improving availability of medical review panels.

Puzzling aspects of health care reform center around the simple fact that health care recipients are *individuals.* In contrast, the stakeholders range from patients, researchers, policymakers, and the general public at the receiving end of reform, even when in a healthy state. Health care delivery has economic, financial, logistical, and political dimensions and a public health and social scope. Health care delivery is typically a significant expense for a country.

The Commonwealth Fund report "Mirror Mirror: reflecting poorly" (https://doi.org/10.26099/01DV-H208) compares the health care systems of 11 high-income countries by analyzing 71 performance measures across five domains—access to care, care process, administrative efficiency, equity, and health care outcomes. These are drawn from surveys and administrative data from the Organisation for Economic Co-operation and Development and the World Health Organization. Last published in 2021, the report still points to the United States as ranking last on access to care, administrative efficiency, equity, and health care outcomes, but second on care process measures. It is estimated that 16.8% of U.S. GDP is spent on health care.

In the United States, an individual who cannot afford private insurance, for example, from a job loss, applies for Medicaid if they meet socioeconomic criteria, apply for Medicare if they received social security income for at least 2 years, or buy insurance through the Affordable Care Act. The transition from personal experience to structural health coverage expansions is where the sociopolitical realities interfere. For the example listed in this paragraph, the options experienced by the individual rely on states expanding care coverage. This expansion can be done in multiple ways that reflect a country's, state, or community structure and political leanings. In the United States, previously suggested ways to ensure expanding coverage include expanding Medicare coverage to individuals starting the age 60 instead of 65, Medicare for all or other inclusive plans, or expanding Medicaid. The tenet of Medicare for all (or any name that one chooses to select for a reform campaign) would be controlling the prices paid to physicians, hospitals, and drug companies. This would theoretically be achieved by reducing administrative costs, including insurance overhead and profits. Thus, Medicare for All or equivalent plans could be the equivalent of quasi-universal coverage.

To put things in perspective, let us look at the dimensions from the Commonwealth Fund report, then compare them to the triple aim espoused by the ACA:

- **Access to care** includes measures of whether an individual can afford proper health care and if they can get this health care in a timely fashion. Affordability of health care is linked to timeliness because seeking emergency services will usually be linked to worse care outcomes and higher expenses. Countries that do well in that respect usually provide some sort of universal health care formula. While never without criticism, those universal access programs avoid desperate emergency service use as a last resort. This measure includes access to after-hours and weekend care and insurance denying payments of a claim or paying less than expected, therefore leading to financial issues for patients.
- **Care process** includes measures of preventive care, safe care, coordinated care, engagement, and patient preferences. This aspect has improved tremendously in the United States since the ACA and Patient-Centered Outcomes Research Institute (PCORI) initiatives were implemented. U.S.-specific challenges are cost-effectively maintaining care processes while minimizing care disparities. Additionally, the U.S. ranks lowest in terms of

patients having continuity with the same doctor, which is a concerning measure for individuals, as continuity is associated with better long-term patient outcomes.

- **Administrative efficiency** refers to the bureaucratic processes by which health care provision is managed. Can a physician get their patient’s medications or referrals efficiently or promptly? Can they implement required guidelines quickly when needed? In this measure, the U.S. ranks poorly compared to other wealthy countries, and most physicians rank administrative efficiency as suboptimal. Two aspects of administrative efficiency are subject to reform potentially. One is the administrative burden aspect and how much physicians have to do to schedule and implement treatment. The other is the administrative burden becoming a deterrent for patients to seek care. This links to patients getting more emergency care and further bloating and excess expenditures in the system.
- **Equity and Income-Related Disparities** is a well-known, well-advertised issue in the United States that remains at the forefront of the administrative and political agenda. The ACA implementation has helped bridge the gap, but as of the 2021 data, minorities in the United States still have subpar access to care and poorer health outcomes than their nonminority counterparts and those in other countries. One notable poor statistic in the United States is that maternal mortality is 17.4 deaths per 100,000 live births, whereas the next high-income country (France) has a rate of 7.6 per 100,000 live births.

Table 56.2–1.
Five Periods of American Legislative Activity for National Health Insurance

Dates: Proposed Reform	Benefit	Administration/Financing	Model/Outcome
1912–1919 American Association for Labor Legislation (AALL): Opposed by American Medical Association (AMA), American Federation of Labor, businesses	Medical care, sick pay, funeral expenses for lower-paid workers (<$1,200/year) and dependents	Administered by states; financed by payroll tax collected in regional funds	Model: Social insurance Failed to pass
1946–1949 Wagner–Murray–Dingle Bill: Supported by President Truman; opposed by AMA	Retirement, disability, unemployment, and health insurance: Physician and hospital care	Expansion of Social Security; employer/employee contributions to “social insurance trust fund”	Model: Social insurance Failed to pass
1963–1965 Medicare and Medicaid	Medicare: Hospital care (Part A) physician care (Part B); medications (Part D) Medicaid: Comprehensive health care, long-term care	Medicare administered federally, Medicaid by the states; Medicare financed through Social Security, federal income taxes, and individual premiums; Medicaid financed by general state and federal tax revenues	Medicare: Social insurance model Medicaid: Public assistance (welfare) mode Both programs were enacted
1970–1974 Kennedy–Griffiths Health Security Act:	National health insurance for the entire population	Administered federally, eliminating all public and private insurance; Nixon plan featured employer	Model: Combined social insurance and

President Nixon countered with an employer mandate plan; Physicians for National Health (PHN) proposed “single payer”		mandate, privately administered, plus Medicaid and Medicare; PNH plan financed by federal tax with single fund in each state	public assistance; failed to pass Nixon plan: Maintained public assistance; added social insurance; failed to pass PNH plan: Merged social insurance and welfare; failed to pass
1991–1994 Clinton Health Security Act: Opposed by insurance and pharmaceutical industries and small employers, single-payer advocates; proposed voluntary approaches	Comprehensive health care	Administered federally; financed through governmental funds, employer mandate, and individual mandate (with subsidies); voluntary: Tax incentives for employers; medical savings accounts (MSAs) for individuals	Model: Integrated social insurance and public assistance Failed to pass

From a mental health perspective, suicide rates in the United States have continued to rise for the past 20 years; and while U.S. patients are more likely to accept mental health care, they have less access to mental health professionals and social services. Almost a quarter of individuals in the U.S. report having been told they have anxiety, depression, or another mental issue, but the abundance in diagnosis is not accompanied by effective treatment or mitigation of adverse outcomes such as suicide (https://www.commonwealthfund.org/publications/issue-briefs/2020/may/mental-health-conditions-substance-use-comparing-us-other-countries).

HEALTH CARE REFORM IN THE 20TH CENTURY: A HISTORICAL OVERVIEW

The reform of the U.S. health care system has been periodically and repeatedly proposed since and before the social reforms of President Franklin Roosevelt. Presidents Harry Truman, Jimmy Carter, Gerald Ford, George H. W. Bush, and Bill Clinton all considered and proposed reform plans. Earlier proposals for national health insurance set the framework for these proposals. Table 56.2–1 summarizes the significant periods of legislative activity since the early 20th century and the complex elements involved in the proposals. Earlier proposals coupled health with other social welfare programs; later proposals narrowed in on health care as health care costs increased dramatically in the later part of the 20th century. Proposals were designed on either the model of social insurance or that of public assistance or welfare. As the importance of universal coverage became clear, these models merged. The locus of administration or control of the proposed health insurance programs—by employers, the federal government, or the states—became important. In particular, the most critical issue was the financing of the system: through government funds, the requirement that employers pay for their employees ("employer mandate"), or the requirement that individuals buy their own insurance ("individual mandate").

In the last decade of the 20th century, as health care costs continued to spiral upward, the proposed Clinton Health Security Act generated a tremendous amount of energy but eventually failed to be enacted. Large employers changed their methods of purchasing care, hiring companies to introduce a variety of cost control techniques, generally described as "managed care." Meanwhile, "incremental" measures were taken in the 1996 Health Insurance Portability and Accountability Act, the 1997 Balanced Budget Act, which limited payments to hospitals, and the 2003 Medicare Prescription Drug Improvement and Modernization Act. In addition to providing partial coverage to Medicare enrollees for medications, the latter act provided the Medicare program with the flexibility to introduce more aggressive health care purchasing techniques to control cost. These measures also supported individual incentives to control cost through new insurance models such as medical savings accounts, which combine tax-exempt personal savings for health care with catastrophic insurance coverage. The movement toward "managed care" purchasing did slow the rising costs for a few years, but its requirements were relaxed due to a strong reaction against control by both patients and providers.

Managed Care: A Phenomenon on the Path to Health Care Reform

The freewheeling spirit resulting from having generous public and private financial support for health care from roughly 1950 to 1980 led to a heady time for U.S. medicine. Society supported the clinical advances built on research that promised breakthroughs just over the horizon. Practitioners were, by association, part of this new era, and, as authorities in their professions, their determination of what patients needed was funded almost without question by public and private sources. As resources became limited owing to many factors, such as inflationary pressures and legislation, payers began to question what it was that health care was delivering for the dollar; that is, the issue of value was raised for the first time in the health economic equation by those paying for health care. A corollary of the issue of value was the question of the accountability of practitioners. Subsequent landmark studies demonstrated geographically differing practice patterns and consequently different costs but similar outcomes for the same disorder or disease. This raised the general question of why this should be the case? Other fundamental issues that have emerged include the following: How can access to care be broadened? How can clinical outcomes as a result of health care be improved? What about the uninsured? How can costs be controlled?

Utilization Review

Employers and purchasers embraced the concepts of utilization review and utilization management as strategies to try to ensure that the most appropriate and most cost-effective clinical decisions with the best outcomes were being made on behalf of any given patient. For this discussion, utilization management is considered the global concept that subsumes various aspects of the review process. These days, virtually all care, except for the increasingly rare full fee for service, is under some form of review and management process, whether public or commercial payer.

Some practitioners consider the review process an intrusion into the clinician–patient relationship. The process can be cumbersome, and disagreement about the decisions reached during a review often contributes to resentment. With some justification, practitioners are irked because third parties with no clinical relationship to the patient have the authority to influence the process of care, challenging the practitioners' clinical autonomy. At one point, the clinical criteria used in the review process were considered "proprietary" and not available to clinicians, so they might see how their care process was being reviewed. At the same time, if practices were reasonably standardized and if practitioners had training (or retraining) that was uniform with a focus on (1) diagnostic accuracy, (2) evidence-based, cost-effective practice, and (3) attention to clinical outcomes, perhaps a great deal of the variance seen in practice might diminish, thereby reducing the need for third-party reviews.

Selective Closed Panels and Networks

Another strategy to improve care while reducing costs was to create selective or preferred provider networks in which clinicians applied to become members of the clinical panel of a managed care organization. By applying to be a network provider, clinicians agreed to practice within the guidelines established by the managed care organization. In theory, the network had some degree of compliance and fidelity to the standards of practice of that particular managed care company. However, this was more of an idealized system of care for several reasons. In many parts of the country, the clinical marketplace is highly competitive because of a glut of practitioners vying for limited clinical dollars. Functionally, this means that many individual practitioners may apply to a particular managed care panel because of simple economics (i.e., they need the income) rather than an interest or willingness to practice within a managed care framework. So, there may be little selectivity about a particular panel of providers because the process is more open-ended until the managed care organization has determined there are sufficient providers for a given geographical area. Whether justified or not, some managed care organizations have reputations for being difficult to work with, reimbursing at what is viewed as “low rates.” As a result, such organizations may have difficulty attracting sufficient providers and may be less selective than is preferable. In more affluent areas, some practitioners, especially well-established ones, do not accept insurance of any kind, so utilization review is not part of the overview of their patients’ clinical care.

Care Management and Intensive Case Management

Much psychiatric care is done with persons with chronic mental health conditions. Driven mainly by the demographic realities of an aging population, health reform considerations focus on chronic illness care and the concept of care management and intensive case management, virtually identical concepts. By analyzing the process of care for various disease entities, care management attempts to introduce discrete improvement steps to improve the efficiency and coordination of care, enhance patient compliance, achieve better outcomes, and reduce costs. Care management has been used with chronic illnesses, such as diabetes or hypertension. In psychiatry, care management has been successfully applied to mood and anxiety disorders. However, the high degree of practice variability not only by the provider but also by a geographic section of the country reflects the historic inability and failure of the health care system to incorporate readily and to standardize quality improvement and evidence-based ideas into the system in which clinician, patient, and health system engage.

Managed Behavioral Health Care

In the late 20th century, costs for psychiatric and substance-abuse services rose considerably faster than the costs for physical health care. The effort to instill accountability among practitioners, expect value for payment, improve access, provide cost-effective services, and use to the extent possible evidence-based approaches to treatment to improve outcomes created a backlash by mental health practitioners against managed care. Scandals in the 1980s and 1990s of for-profit managed behavioral health care companies engaging in unethical practices overshadowed the equally scandalous accounts of practitioner excesses of use and inappropriate, often misguided, treatment. Managed behavioral health care became synonymous with denial of care and, in for-profit systems, the image of fat-cat corporate leaders with large salaries and generous stock options derived from the misfortune of patients and beleaguered practitioners, the latter mired in an endlessly confusing system of external review, was readily accepted by many as the only reality. What was missing in the tumult was the perspective that managed behavioral health care was a way station on the path to behavioral health care reform.

Public Sector Managed Behavioral Health Care

Governmental agencies purchase 60% of all behavioral health care at federal, state, and local levels. As resources followed patients out of the state hospitals, much of the state expenditures remained controlled by agencies responsible for specific populations such as mental health, criminal justice, child welfare, and social services. Medicaid, the entitlement program for those unable to afford health care, began in 1965 and is the primary funding source for local governments to pay for public behavioral health care services. Medicaid's overall costs rose dramatically by 2000, accounting for more than 15% of all U.S. health care costs, with behavioral health care accounting for about 10% of Medicaid spending.

Medicaid's behavioral health costs became a severe liability at the state or county government level because of yearly cost overruns. As a result, government agencies turned to managed care contracting of Medicaid services to shift risk to nonprofit behavioral health care provider organizations, thus limiting the state's liability.

State governments also soon learned that they could redirect the bulk of their behavioral health expenditures for severely disabled persons in the categorical agencies into the Medicaid program, thus increasing their match base for the Medicaid Federal Financial Participation (FFP) and leveraging federal revenues into their state general fund. Medicaid expenditures continued to increase, and this was a major contributing factor to the 100% increase in public mental health dollars from 1956 to 2003. The downside from the point of view of the seriously and persistently mentally ill was that the control of these services went from the public agencies responsible for behavioral health care to commercial managed care companies whose networks and capacities were more in tune with the needs of employed populations.

Safety-net hospitals, community mental health centers, and academic medical centers were under extreme financial distress and endured substantial service limitations. Thus, while public sector experiments with large-scale managed behavioral health care produced some successes, costs, and quality of care continued to be problematic.

Private Sector Managed Behavioral Health Care

Government deregulation of the hospital industry enabled the astronomical growth of for-profit mental health and substance abuse facilities, many organized as large hospital chains. As a result, the use of mental health and substance abuse treatment increased dramatically, exemplified by the fourfold increase in adolescent inpatient admissions between 1982 and 1987. The proliferation, financial success, and perceived abuses of proprietary psychiatric hospitals caused great consternation among employers, insurers, legislators, and the public. Many hospitals, including presumably less exploitative, not-for-profit hospitals, seemed to provide treatment based on reimbursement potential rather than actual medical necessity. One of the physician pioneers of the managed behavioral health care industry commented that it was a myth that substance abuse treatment required a fixed length (usually 28 days) of inpatient treatment. Rarely has such a fixed false belief had so little factual support or received such fervent adherence. As early as 1983, a report from the Office of Technology Assessment that the literature failed to demonstrate a general superiority of inpatient over alternative treatment settings, as measured by outcome. Subsequent studies have confirmed that hospital or residential treatment is neither necessary nor sufficient for most people with substance use disorders.

Nevertheless, long inpatient stays for adolescents with behavioral or substance abuse problems became common. Inappropriate hospitalizations for excessive periods became exposed as proprietary systems flourished. Health care payers (employers, insurance companies, Medicare, and Medicaid) became quite rightly concerned by the rising costs and the suspect practices. They questioned the actual medical necessity of costly services such as extended psychiatric inpatient stays. The psychiatric profession also successfully argued that inpatient stays for psychiatric patients could not be actuarially determined with any precision, thus making federal Medicare mental health inpatient criteria exempt from federally determined diagnostic-related groups (DRGs) for reimbursement purposes. In this climate, it became more and more challenging to maintain adequate oversight or regulation of mental health and substance abuse treatments. Private employers became the first to respond proactively to these concerns by contracting with the pioneer entrepreneurs of the first generation of managed behavioral health organizations (MBHOs) led by mental health professionals who had the credibility and specialized knowledge and skill to provide oversight of mental health and substance abuse practitioners.

This initial phase of managed behavioral health care (approximately 1983 to 1987) began with traditional indemnity insurers changing benefit designs in the hope of discouraging excess use. Tactics included limiting mental health coverage for specific disorders or treatments and instituting deductibles, copayments, and benefit maximums. These efforts were ultimately all unsuccessful. Entrepreneurial companies, led by psychiatrists and psychologists, began their entry into the health care marketplace through contracts with HMOs struggling to administer behavioral health care benefits. These initial efforts' dramatic success was driven by the limitation of access to mental health and substance abuse services. Access was limited through tight medical management (e.g., instituting strict medical necessity criteria for level-of-care determinations, limiting authorizations for inpatient admissions and continuation of stay, or the proliferation of denials of payment for care), as well as by restricting the network of caregivers and institutions credentialed to provide care for the population covered.

The first phase of limitation of access, aimed at restricting access for patients, was successful but led to dramatic customer complaints. As large employers (not HMOs) became the target for MBHO marketing, patient choice was increased by expanding provider networks, but overall costs were now saved through a dramatic reduction in rates paid to providers. Typical discounts were 20% to 25% of professional fees and 25% to 35% of hospital charges. These discounts seemed Draconian at the time and were widely seen as threats to behavioral health care providers' solvency, but more significant fee reductions were to come. This network expansion and reduction of provider rates characterized the second phase of the managed behavioral health care revolution (approximately 1993 to 1998).

The third phase (1998 to the present) has been termed the phase of industry consolidation. The proliferation and financial success of MBHOs in the 1980s and early 1990s led to the development of administrative models, information system infrastructure, extensive provider network management techniques, and sophisticated medical management strategies that resulted in significant economies of scale. Nevertheless, provider rates continued to fall, along with profit margins. Utilization patterns also changed dramatically. In tightly managed markets (such as Minneapolis and Los Angeles), the average commercial inpatient days per 1,000 members declined: from approximately 150 in 1983, 75 in 1990, and 10 to 15 in 2000. The cost to employers of behavioral health care under traditional indemnity plans was approximately $9 per member per month. By 2000, these costs fell dramatically to less than $3 per member per month. To sustain these reductions, the MBHO industry experienced dramatic consolidation. Within a few years, through mergers, acquisitions, and market growth, the industry became concentrated into a small number of very powerful behavioral health care corporations.

HEALTH CARE REFORM IN THE 21ST CENTURY

Whether admired or not, many of managed care's innovations are irreversible. Managed care's financial success was dramatic (i.e., decreased behavioral health care costs). Utilization management by managed care companies led to significant decreases in the average length of inpatient stays for psychiatric patients and fewer total inpatient days for populations of patients as a whole. Despite widespread complaints of diminished physician, hospital, and patient autonomy, constraints of decreased physician and hospital reimbursement, and anecdotal horror stories of sacrificed patient health care quality, there is no systematic way of convincing lawmakers that managed care destroyed the quality of the U.S. health care system and no easy way to reverse the changes that have happened to medical practice in general and psychiatric practice in particular. One could reasonably argue that the health care system was already imploding, which was the impetus for yet another effort at reforming the system. The National Committee on Quality Assurance (NCQA) points to significant improvements in health care quality resulting from efforts at self-improvement by the managed care industry when these are conducted properly. Managed care contributed to health care quality by emphasizing population-, evidence-, and guideline-based health care, chronic illness care management, and information technology to evaluate and change the process and outcomes of care.

However, by the beginning of the 21st century, health care costs continued to spiral upward in the United States, and health care quality remained substantially below standards set in other comparable affluent societies (see Table 56.2–2). With overall health care costs rising at more than twice the inflation rate, employer groups could not sustain the resultant increase in premiums.

Waste in Health Care

In recent years, considerable attention has been paid to eliminating waste in U.S. health care, not just redesigning a dysfunctional health care system with improved access, better quality, improved efficiency, expanded coverage to enhance equity, and lowered costs. It has been estimated that a third of the annual health care expenditure ($2.8 trillion in 2014) could be eliminated without any adverse health consequences to individual patients. Unnecessary administrative expenses, care that provides little or no value, costs associated with medical errors, and fraud are examples of waste. There have been six areas identified that are responsible for the waste:

1. poor care delivery
2. poor care coordination
3. excessive care
4. excessive administration
5. pricing failures
6. fraud and abuse

These six areas were projected to push U.S. health care expenditures to 20% of the gross domestic product by 2020. Not surprisingly, therefore, in the first two decades of the 21st century, the urgency of health care reform has intensified as the growth of U.S. health care spending is projected to double in 8-year intervals representing almost 18% of the gross domestic product in 2011. The competitive position of the United States in the global economy is threatened, and many argue that the economy cannot be fixed until health care is fixed. Influential reports show that the United States spends considerably more on health care than any other country. This growth in spending consistently outstripped collective income. Yet the United States ranks poorly among industrialized countries in standard measures such as life expectancy and infant mortality. Moreover, it cannot provide health insurance to at least 15% of its population. Therefore, health care reform will remain at the forefront of the domestic agenda as long as the path of sustainability has not been achieved.

THE IMPACT OF THE AFFORDABLE CARE ACT (ACA) AND THE TRIPLE AIM DEFINITION—APPLICATIONS TO MENTAL HEALTH

“Between the health care we have and the care we could have lies not just a gap, but a chasm.” IOM, 2001

The key provisions of the ACA are designed to:

- Provide coverage for more people
- Provide more benefits, better protection, and transparency
- Lower costs for consumers and government
- Provide quality and efficiency
- Provide a stronger workforce and health care infrastructure.
- Provide a greater focus on public health, prevention, and chronic illness care
- Support innovative techniques and technologies

Meeting the three inter-related concepts (1) improving the experience of care, (2) improving the health of populations, and (3) reducing per capita costs of health care is required to achieve high-value care as reform shifts from a *volume-based* to a *value-based* system. The passage of the ACA as law in 2010 laid the foundation for health care transformation. Key policy reports in the first decade of the 21st century sparked the need for the ACA, including the influential report of the Institute of Medicine (IOM), in 2001: “Crossing the Quality Chasm: A New Health System for the 21st Century.” The report highlighted the disparity between best practice and current practices in the United States and the effect on widespread variability and escalating health care costs. It established Six Aims for the 21st-century health care system, espoused by the ACA.

The larger health care systems in which psychiatrists and other behavioral health specialists work profoundly impact the delivery and outcomes of psychiatric and physical health care services. Internationally, and over the last two decades in the United States, the dominant theme in health care system reform shifted from an emphasis on managed care to a tripartite focus on patient-centered care (as a complement to provider-driven disease management), improvement of the health of entire populations with interventions tested in comparative effectiveness research (CER) (as opposed to individual-level observational or clinical trial research), and the development of incentives to maximize health care cost-effectiveness (as opposed to containing costs by restricting access to or reimbursement for health care). The Triple Aim has served as a foundation for health care reform, and we are now in a place to examine some of its effects a decade later (see Fig. 56.2–1).

The guiding principle of the Triple Aim is that health care quality should be defined based upon the vantage of the recipient, *the patient*, and not externally by technical or clinical considerations. Beginning with a patient-centered (as opposed to disease-based) perspective, health care must be teamed up with public health (i.e., prevention and health promotion) and social services to fully meet the needs of individuals and families and create a healthy overall population. This biopsychosocial approach integrates otherwise fragmented or missing services and makes primary (rather than specialty) health care the driver for delivering services—containing and reducing costs and promoting health. The implementation of this system has been arduous and carried its own challenges. The concepts of patient-centeredness and equity are not new or radical but have been recurrent themes in health care reform efforts in the United States for more than a century. They have been the bedrock and the foundation in the more successful health care systems in other affluent and industrialized countries internationally.

For psychiatry, specifically, the impact of patient-centered care is far-reaching given the fact that individuals with serious mental illness (SMI) represent an undue large portion of underinsured or uninsured patients and have multiple co-occurring nonpsychiatric disorders, e.g., medical, addiction disorders, in addiction to negative social determinants of health.

Expanding the concept of best practice to include public health and prevention efforts and coupling this with chronic illness care management are among the key points of the IOM monograph and are aligned with ACA triple aim, as are the pivotal roles of preprofessional training the retraining of the existing workforce. With finite resources for health care amid competing priorities, the reformed health care system and, specifically, the reformed behavioral health care system must find ways to integrate effectively multiple factors, such as (1) practitioner, system, and patient accountability; (2) economic support for public health efforts, such as prevention and early identification; (3) the linkage of acute care with chronic illness care/collaborative care/coordinated care management; (4) improved access; (5) effective integration with primary and specialty care; (6) development of models of the most clinically effective and cost-effective care (e.g., integrated with public and physical health, interdisciplinary in practice, with continuity of care across venues); and (7) meaningful involvement of patients and, where feasible, their families, in the process of care. Managed care can be viewed as a sign and a symptom within the broader construct of health care reform. The creation of medical homes has been the *first step* toward this integration.

Numerous studies have shown the high prevalence of behavioral health conditions in physical health. Patients with comorbid illnesses (mental, substance use, and physical health disorders) represent the most costly group in health systems. Many of these individuals are seen in public sector systems, often incarcerated or homeless with inadequate physical and behavioral health care.

A dramatic example of the need to find ways to integrate primary care and behavioral health care in coherent delivery systems is the “dual eligibles,” that is, the Medicare and Medicaid eligible population. This group is among the most costly of any population of patients, not only because a large portion of the poor and very older adult patients are in long-term care (nursing homes and hospice), but also because those in the community find it difficult to negotiate consistent access to health care due to their disabilities. Typically, a given state might find that 40% of their dual-eligible population have serious and persistent mental illnesses.

Sadly, real obstacles remain in reforming health care related to mental health outcomes. The National Committee for Quality Assurance (NCQA) reported that despite essential strides made in the general medical and surgery sectors, there continued to be disturbing exceptions to overall health care quality improvement in mental health, that the situation remained poor and concerning with individuals afflicted with SMI dying 7 to 10 years earlier than their non-SMI counterparts. The IOM’s recommendations centered first on linking mental health and substance use treatment more closely with general medical care; second, the details of the original Quality Chasm report, its aims, rules, and redesign approaches, should be operationalized in the treatment of mental health and substance use disorders. Inadequate leadership and resources have been cited along with these areas having fewer objective, standardized diagnostic methods compared to physical health disorders; weakness of the evidence base for supporting quality measures; lack of coherent strategies for adopting quality measures that get back to the problems in leadership in assuming this responsibility to move the field along. *Fewer than 5% of the National Quality Forum’s list of 650 quality indicators relate to the care for individuals having mental health and substance use problems*.

The 2001 IOM Quality Chasm Report articulated a strategy for health care improvement in a separate report for mental and substance use disorders because it has numerous distinctive characteristics. These distinctive characteristics include the greater stigma associated with mental and substance use conditions, more frequent coercion of these patients into treatment, a less developed system for measuring quality and improvement, a more educationally heterogeneous workforce, the fragmentation of the behavioral health care system with inadequate communication and coordination of care among its components, and a perverse funding structure.

In its report “Improving the Quality of Health Care for Mental and Substance Use Conditions” (2006), the 10 items listed as guidelines/priorities for mental health and substance use conditions are as follows:

1. Care is based on continuous healing relationships.
2. Care is customized to patient needs and values.

3. The patient is the source of control.
4. Knowledge is shared, and information flows freely.
5. Decision-making is evidence-based.
6. Safety is a system responsibility.
7. Transparency is necessary.
8. Needs are anticipated.
9. Waste is continuously decreased.
10. Cooperation among clinicians is essential

The report also noted the considerable societal and workplace burden that mental and substance use conditions bring with substantial employer costs from absenteeism, “presenteeism” (i.e., being at work but essentially not functioning fully), sub-par educational achievement by children having such conditions leading to a variety of emotional and behavioral problems. Children with poor educational achievement enter a cycle of emotional and behavioral problems leading to risk for delinquent and antisocial behaviors, dropping out of school, eventually affecting the child welfare and juvenile justice systems. This, in turn, becomes a feeder phenomenon into the adult justice system that has seen an increasing number of inmates in prisons and jails with mental and substance use conditions. The U.S. Bureau of Justice Statistics estimated that 16% of all persons in jails and prisons have a mental or substance use disorder. Systematic assessment studies document prevalence estimates that are twice as high, with as many as one in three incarcerated adults and youths having a behavioral health disorder.

An overriding theme throughout the report was that treatment can be effective and that recovery is possible. The report noted that quality problems hinder effective treatment and recovery, noting that numerous studies have shown the discrepancy between what is considered effective care and what is provided, echoing the Quality Chasm report. Low adherence rates to clinical practice guidelines and evidence-based practice standards were noted across major diagnostic categories. For example, adequate adherence rates to established practice guidelines occurred in only 27% of studies covering alcohol withdrawal, bipolar disorder, depression, panic disorder, psychosis, schizophrenia, and substance use.

Parallel programs targeting the same priorities for integrative mental health care in the United States are discussed below.

The Chronic Care Initiatives in Health Maintenance Organizations

These aim to change physician and patient behaviors in several ways, including

- Moving from a focus on a cure to symptom relief
- Expanding the boundaries of care among providers and between traditional medical and social services

- Making the patient a critical part of the care process through shared decision-making:
    - Creating active roles for the patient’s significant others
    - Tying patient satisfaction to clinical outcomes

Building Health Systems for People With Chronic Illnesses

Sponsored by the Robert Wood Johnson Foundation, this program attempts to better coordinate medical and supportive services for the chronically ill and, in so doing, challenges the fact that most insurance systems tend to fund acute care rather than supportive care for individuals with chronic conditions. The program attempts to do the following:

- Integrate services that care is provided across diverse settings; systems of care link clinical and nonclinical support services.
- Reallocate resources by redirecting existing and acute care—focused delivery and financing to serve the chronically ill better.
- Promote early medical and nonmedical interventions.
- Help individuals maintain independence as long as possible in their homes and communities.
- Give the chronically ill and their caregivers a role in designing and improving their health care and support services.
- Support the development of models of care that people with different chronic health conditions can use.

The demonstration program in the accompanying text box set the stage for two operational models for fundamental system changes to improve quality and outcomes. Many proposed and expected system reforms surround efforts to implement the chronic illness care model and the collaborative care model. The chronic illness care model was first elaborated and tested for chronic general medical illnesses such as diabetes, congestive heart failure, and asthma. Recent efforts have attempted to apply the principles of chronic illness care to depression in primary care settings. On the other hand, the collaborative care model was first described and tested for depression in primary care and has been broadened for other psychiatric illnesses that can also be treated in general medical settings with care managers and psychiatrists’ support, such as panic posttraumatic stress disorder.

The 2008 Mental Health Parity and Addiction Equity Act

The Mental Health Parity and Addiction Equity Act enacted in 2008—the Wellstone-Domenici Parity Act—tightened the requirements for parity laid out in the Mental Health Parity Act of 1996. Parity was designed to bring individuals with behavioral health disorders into the mainstream U.S. health care system to correct the historical inattention and inequality of care in this population and reduce the stigmatization such individuals experienced compared to people having physical health problems alone. The intent was to have behavioral health care benefits equivalent to medical and surgical care benefits. In addition, about two-thirds of primary care physicians had reported difficulty in accessing outpatient behavioral health services for their patients, a rate twice as high as that for other services. Lack of coverage or inadequate coverage, health plan barriers, and a shortage of behavioral health providers were cited by primary care physicians as problems contributing to accessing good behavioral health care. The Mental Health Parity and Addiction and Addiction Equity Act required group health plans with behavioral health benefits to provide the same level of coverage as physical health plan coverage. Access to behavioral health services has been particularly problematic for low-income uninsured and Medicaid patients. Ironically, primary care physicians practicing in areas with many psychiatrists had a greater probability of not securing behavioral health services for their patients because of various plan barriers and the inadequacy of coverage these patients had. Recent studies show that psychiatrists, compared to all other areas of medicine, have the lowest acceptance rate of Medicare (i.e., less than 50% of psychiatrists accept Medicare, with figures lower still for Medicaid). The speculation about such an observation its effect on how other specialties, professionals, trainees, policymakers, and the general population, view adherents to such a practice is important to consider. Some have advocated tying partial or total medical school debt-forgiveness, or even state medical licensure, to having a reasonable percentage of one's practice tied to practitioners seeing individuals covered by Medicare and Medicaid.

The ACT's effect was the practical disappearance of quantitative treatment limits (QTLs), which insurance companies frequently used to limit such treatments and improve coverages for substance use and mental health conditions. More help-seeking in adults suffering from mental health disorders, substance abuse, and eating disorders were noted after parity laws were mandated but with the main caveat that out-of-pocket expenditures also increased. From a limited perspective, the parity acts of 1996 and 2008 were successful. However, from a more global view, they still did not meet the needs of reform in terms of care access, administrative burden, and, more importantly, equity needs (Table 56.2–3).

IMPROVING MODELS IN HEALTH CARE: THE ACA A DECADE LATER

Patient-Centered Medical Homes and Medical Neighborhoods

In 2007, the American Academy of Family Physicians, the American Academy of Pediatrics, the American College of Physicians, and the American Osteopathic Association issued joint principles for the Patient-Centered Medical Home (PCMH), a model to provide comprehensive primary care to children and adults, where appropriate care is structured, delivered, and coordinated around the specific needs of each patient. The American Academy of Pediatrics originally developed the medical home model in 1967 for children with special health needs, where it was essential to have a centralized location for a child's medical records. The joint principles of PCMHs (personal relationship with licensed providers, team approach, comprehensive/whole-person approach, coordination and integration of care, quality and safety, expanded access to care, added value recognized, are all hallmarks) cover many of the characteristics of Accountable Care Organizations (ACOs) where PCMHs are seen as the building blocks for ACOs.

Table 56.2–3.

Summary of the Institute of Medicine's Recommendations of Care for Individuals With Mental and Substance Use Condition

1. Emphasize patient-centered care and the importance of supporting patient decision making and preferences	The current health systems place a number of barriers to patient-centered care. Insurance discrimination is manifested by less benefit coverage for mental and substance use (M/SU) conditions. There are higher copays for these services. ▸ Clinicians, organizations, accrediting bodies, health plans, and payers need to support a patient-centered care (PCC) approach that respects decision-making capacity of patients. ▸ Stereotypes of patients being unable to arrive at decisions have resulted in coercion of care and discrimination historically.
2. Improve the infrastructure for quality improvement and evidence-based care	Significant problems with the current infrastructure for quality improvement. Assessment and treatment practices not well codified and captured in administrative data sets. Outcome measurements not widely applied; performance measurement for M/SU health care receives insufficient attention in the private sector; public sector efforts have not yet achieved consensus. Quality improvement methods are not permeating day-to-day service. This leads to systems of care that are not based on the principles of quality measurement, and they fail to demonstrate continuous improvement.
3. Coordinate care across systems of care	Poor linkages across systems of care; there is general fragmentation between M/SU and general health care and between mental and substance use care for both children and adults. Unclear accountability for coordination of care among providers.
4. Ensure that the National Health Information Infrastructure Initiative (NHIII) benefits people with mental and substance use conditions	M/SU conditions are not well incorporated into the strategic design of the NHIII. The proposed solutions are as follows: ▸ Charge the Office of the National Coordinator of Health Information Technology and the Substance Abuse and Mental Health Services Administration (SAMHSA) to jointly develop a plan that addresses M/SU health care.

	▸ Leaders in M/SU health care should become proactive in the national process to set health care data and information technology standards. ▸ Public and private purchasers of health care should decrease the burden of variable reporting and billing requirements. Public and private purchasers of health care should encourage widespread adoption of electronic health records, computer-based clinical decision support systems, computerized order entry, and other forms of useful information technology.
5. Increase the workforce capacity	A crisis in the M/SU workforce exists. There is greater variation in the quality of the M/SU workforce than in that for general health care. There are across-the-board deficiencies in education, and there is no “core knowledge” base across disciplines. The resulting variation in licensure, credentialing, and continuing education across disciplines does not assure agreed-on core competencies or adherence to the same standards of practice. The remedies include the following: ▸ Creation of an ongoing, federally funded public–private Council on the Mental and Substance Use Health Care Workforce. ▸ Collaboration of the Council with institutions of higher education, licensing and accrediting bodies, purchasers, and other private sector initiatives developed by the Association for Medical Education and Research in Substance Abuse (AMERSA) and the Annapolis Coalition (http://www.annapoliscoalition.org).
6. Restructure the marketplace to promote incentives for quality and improvement	The Institute of Medicine (IOM) report finds problems in the way in which M/SU care is purchased. Government (state and local) purchasers dominate, and frequently insurance is purchased for M/SU health care separately from general health care. This results in “carve-out” arrangements. Private insurance tends to avoid coverage or offers more-limited coverage to

individuals with M/SU illnesses. Government purchasers often use direct purchasing by contract rather than insurance arrangements.

- Government should pass laws designed to enact coverage parity by purchasers so that individuals with M/SU conditions are not discriminated against when enrolling in health plans.
- Examples of tools that could be used to bring about parity are risk adjustment, payer carve-outs, risk-sharing or mixed-payment contracts, and benefit standardization across health plans.
- State-level procurement for M/SU care should give the greatest weight to quality and use M/SU health care quality measures in procurement and accountability.
- State and local governments should reduce emphasis on grant-based systems of financing and increase the use of funding mechanisms that link some funds to measures of quality.

Data from the Institute of Medicine. *Crossing the Quality Chasm: Adaptation to Mental Health and Addictive Disorders*. National Academies Press; 2006.

Some of the more recent literature suggested that early PCMH interventions led to only modest improvement in quality and patient experience, with little evidence of effects on costs and no reductions in utilization of hospital, emergency, or ambulatory care services over 3 years. At the same time, these studies suggested that refinement of the outcomes associated with PCMHs was needed and that the development of the NCQA standards for medical home recognition had not been fully developed applied in the early PCMH development. Nonetheless, the studies concluded that further PCMH development and function refinement was necessary.

As the conceptualization of the organization of health care delivery systems developed, it was logical that the PCMH model would expand to include a constellation of entities and activities responsible for the care of populations of patients. Thus, the concept of the Medical Neighborhood was spawned encompassing PCMHs with comprehensive primary, secondary, tertiary services that are community-based, responsive to the needs of individual patients at different times, a truly integrated system of care with good coordination, effective communication, attention to patient education, and cost-effective. Such a concept forms the basis for accountable care.

Accountable Care Organizations

With the advent of the ACA, the Department of Health and Human Services (DHHS) began developing new approaches in conjunction with the private sector to improve care and to meet the Triple Aim for Medicare and Medicaid recipients. ACOs are voluntary groups of physicians, hospitals, and other health care providers that assume responsibility for a defined population of patients based on the population's use of primary care services. The ACO is responsible for the entire continuum of care that the defined population of patients might need, including access to specialists, social services, public health, and assessment of other socioeconomic factors such as housing, transportation, education, poverty, and nutrition. Providing preventive care for all patients and case management for individuals with chronic diseases is a component of an ACO. If the ACO succeeds in delivering high-quality, improved care at a lower cost, there is an incentive built into the model whereby the ACO can share in the savings achieved through meeting the Triple Aim. Under the ACA, an ACO agrees to manage the health care needs of a minimum of 5,000 Medicare beneficiaries for at least 3 years. Under an ACO, providers are held accountable for the health of their patients and have strong incentives to cooperate and create savings by avoiding unnecessary care (see below). Functionally, ACOs need to be fully integrated through an electronic medical record to share needed information among providers. Different ACO models exist to give hospitals and clinicians choices in working with one another. This process, initiated in 2010, is still ongoing with many hurdles.

The Teaching Health Center

There has been interest in providing post-graduate medical education (post-GME) in the primary care environment of the Federally Qualified Health Centers for some years. These programs have demonstrated that physicians trained in these settings are three times more likely to work in Federally Qualified Health Centers (FQHCs) and twice as likely to serve underserved areas of the country. The ACA provided funds to establish Teaching Health Centers training physicians in nine primary care–related disciplines (including Psychiatry). In the same vein, the IOM issued a report in 2014, "Graduate Medical Education That Meets the Nation's Health Needs," calling for the reform of financing, governance, and transparency of GME. The Report called for a 10-year transition period in which the current funding for more traditional residency programs will be modified. As a result, transformative and innovative residency programs will be created and supported in primary care settings and interdisciplinary organizations providing intensive care programs for persons with severe disabilities and multiple chronic illness conditions.

On the surface, the idea of involving learners in the new model was attractive, but the funding was not consistent, and funding instability limited the impact of this program. It remains an attractive target for further reform. The Teaching Health Center can also meet the need for medical innovation programs in rural areas, improving processes on multiple levels and using alternative funding.

Comparative Effectiveness Research and Patient-Centered Outcomes Research

CER and patient-centered outcomes research (PCOR) are essential to fulfilling each of the three goals of the Triple Aim and correspondingly have been allocated substantial funding support by the ACA through the Patient-Centered Outcomes Research Trust Fund (PCOTF). PCORTF received funds from the general fund of the Treasury and a small fee assessed on Medicare, private health insurance, and self-insured plan revenues. The PCORI received approximately $3.5 billion from the PCORTF over ten years ending September 30, 2019 and used those funds to build the capacity of the health care system to provide and evaluate patient-centered and outcome-driven services. The remaining 80% of PCORTF funds were transferred to the Agency for Healthcare Research and Quality (AHRQ) to support and evaluate PCOR in U.S. health care organizations.

PCOR is intended to provide methods and data repositories that can inform health care services by monitoring key health outcomes. Critical research questions for this agenda include how patients, families, and clinicians deal with the complex and often confusing choices involved in achieving and sustaining health, preventing and treating diseases and other health problems, and accessing and navigating health care systems. Traditional medical research has produced vital advances in understanding disease conditions and their treatment. However, it has not been intended or designed to enhance the current understanding of how patients subjectively experience, participate in and are affected by health care and interactions with health care providers. Patient-centered medical research does exist, but its results typically are not systematically disseminated to either clinicians or patients and families. Research linking the patient's involvement in health care and health outcomes also exists. However, its findings have not been extended beyond demonstrating that a collaborative provider–patient relationship plays a crucial role in patient motivation, adherence, and clinical and functional outcomes. PCOR takes on these critical questions that patients and their clinicians face daily in health care encounters and their personal lives. PCOR is a systematic approach to patient-centered CER, in which patient and clinician preferences, choices, actions, and interactions are studied to determine tools, strategies, resources, and courses of action associated with cost-effective health care outcomes. For patients, PCOR involves testing and then providing guidance about which approaches to care work best, given their particular health conditions, personal and familial concerns, socioeconomic circumstances, and sociocultural preferences. PCOR is designed to provide evidence-based guidance addressing the questions they face daily in practice for clinicians. For insurers, PCOR produces evidence to help them make the best decisions on improving health outcomes for their members while also containing costs, especially with high-burden, high-impact disease conditions.

For psychiatry and the broader mental health field, PCOR provides opportunities and an impetus to conduct real-world clinical research on topics such as these recently funded PCORI projects:

- Integrative Medicine Group Visits: A Patient-Centered Approach to Reducing Chronic Pain and Depression in a Disparate Urban Population
- A Community-Based Executive Function Intervention for Low-Income Children with ADHD and ASD
- Improving Transitional Care Experience for Individuals with SMI
- A Helping Hand to Activate Patient-Centered Depression Care among Low-Income Patients (AHH)
- Integrated Care and Patient Navigators for Latinos with SMI
- Patient-Centered Trauma Treatment for PTSD and Substance Abuse: Is It an Effective Treatment Option?

Pay for Performance, Public Reporting of Performance, and Meaningful Use

The effort to improve quality and, therefore, outcomes has taken many guises, from revamping training to produce clinicians and systems that practice in a quality paradigm to imploring clinicians and systems to do the right thing. At its most basic level, change can also be brought about by behavioral shaping and the use of incentives and disincentives to achieve the desired result—in this case, quality improvement and patient-focused, high-quality care. Two such initiatives, Pay for Performance (P4P) and Public Reporting of Performance (PR), are designed to achieve these results. P4P and PR have been common in physical health care for several years. CMS has adopted P4P and has launched initiatives to demonstrate different ways to implement it. More than half of commercial health maintenance organizations use P4P, and the acceptance of performance measurement among physicians and organized medicine has been acknowledged if not fully realized. P4P and PR, in essence, link physician reimbursement and nonmonetary rewards to improve the quality of care. In addition, physicians recognized for providing high-quality care and more efficient care deliver it at a lower cost than physicians who do not participate.

P4P and PR can reward health plans, provider groups, and individual clinicians in varying ways. Payment is made based on meeting prespecified goals. P4P has had a limited presence in behavioral health, but efforts to expand it into common disorders such as depression and substance use disorders have received considerable attention. For example, a P4P paradigm in behavioral health might involve the percentage of patients diagnosed with a new episode of depression who were treated with an antidepressant at an adequate dosage, who were given the medication for a full 12 weeks; or patients who are given at baseline and subsequently, the Patient Health Questionnaire (PHQ), where the scores are used, along with routine clinical assessment, to track response to treatment over time. If P4P and PR achieve similar penetration in behavioral health care as in physical health care, then the modeling for this approach ideally would begin in training programs.

In mental health, P4P is risky as it may enhance specific outcomes but undermine the essence of psychiatric treatment and the comprehensive totalistic humane view of the patient. Additionally, it has been linked in nonmedical organizations to increasing employee stress and anxiety, so the effect on physician burnout remains unknown but could be harmful if P4P becomes widely implemented or the de facto practice model. A large meta-analysis of P4P in 12 countries between 2010 and 2018 shows that the effect of P4P is significant if both cost and quality are included but often has unintended consequences and smaller effect sizes than intended.

Behavioral Health Care Services for Children With Serious Emotional Disorders

Children and adolescents with serious emotional disorders (SEDs), such as those with suicidal depression or early-onset psychotic disorders, represent another specialized population. On an annual basis, approximately 2% to 3% of children 3 to 5 years of age and 6% to 9% of children 6 to 17 years of age use mental health services. Of these, only a small percentage is defined as having SED, approximately 0.5%. These children, particularly adolescents, often require complex case management and intensive (e.g., residential or inpatient) services that are costly to provide and pay for.

The most problematic aspect of caring for children and adolescents with serious emotional disturbances is that five categorical agencies are responsible for providing it. Child Welfare has the largest group of these children and the largest budget. Special Education obligations in local school districts are second in expenditures. Mental Health agencies have a clear mandate but less funding despite usually caring for those in greatest need. Juvenile Justice programs serving youth who come before the courts and General Health and Primary Care systems often are the first to identify children with SEDs. However, these tend to operate separately from mental health specialty services and rely on psychotropic medications even though psychosocial treatments are considered the first-line intervention for most pediatric and adolescent psychiatric disorders.

This division of responsibility for child and adolescent services makes it very difficult to organize a coherent delivery system, and in most jurisdictions, confusion and fragmentation are the rule. In the 1990s, following a decade of National Institute of Mental Health (NIMH) planning grants, the Robert Wood Johnson Foundation developed the Mental Health Services Program for Youth (MHSPY) to come up with coherent systems of care for children with SEDs and their families, integrating the efforts of the responsible agencies at the community level. This was followed by a large grant program by the Substance Abuse and Mental Health Services Administration (SAMHSA). A number of the more than 80 communities that received these grants have developed advanced care management program models providing individualized, intensive care services to children (and their families) who might otherwise have been confined in institutional settings. Services under these models are often funded by risk-adjusted case rates derived from the blending of funds from different agencies' budgets and often administered by the Medicaid program. A compelling high-cost, high-need group that can potentially benefit from the integrated care provided under health homes is children with SEDs were identified in a 2014 policy brief by the Center for Health Care Strategies as:

> The Medicaid health home state plan option is designed to provide a comprehensive system of care coordination across medical, behavioral, and long term services and supports for Medicaid beneficiaries with chronic physical or serious mental health conditions . . . states can tailor behavioral health-focused health homes to meet the unique needs of both children and adults. (Center for Health Care Strategies 2014 policy brief. https://www.chcs.org/media/Developing_Health_Homes_for_SED_02_27_14.pdf.)

The health home is envisioned as a comprehensive set of services that wrap around the patient and address the full range of complex health problems. This could include pediatric, psychological, educational, behavior modification, case management, social work, family therapy, child welfare, legal/juvenile justice services, and psychiatry for children with SEDs. When working within the health home rubric with children, psychiatrists play a vital leadership role in collaboratively informing and coordinating with multiple behavioral health and social/educational services providers as well as with the pediatric primary care provider.

HEALTH INFORMATION TECHNOLOGY (HIT) AND ELECTRONIC HEALTH RECORDS (EHR)

> "By computerizing health records, we can avoid dangerous medical mistakes, reduce costs, and improve care." *President George W. Bush, State of the Union Address, January 20, 2004.*

Two successive administrations, Bush and Obama, have taken on the task of improving health records and communications. The 2009 American Recovery and Reinvestment Act (ARRA) and the related Health Information Technology for Economic and Clinical Health (HITECH) Act were designed to improve the widespread implementation of electronic health records. These acts represent wide-ranging public investments to help expand EHR utilization and expand HIT use to big data analysis. By modernizing the health care field, the hope is to improve population health, decrease medical errors, streamline financial reimbursement, and streamline billing activities. Another advantage of HIT adoption is the creation of more jobs in that health care technology sector, thereby simplifying and vitalizing a new economic sector that, until ~2008, was fairly limited. Expansion of that sector benefits HIT vendors, the data analytics sector, academic medical centers, professional bodies, and universities.

On the other hand, HIT could see major expansions with the advent of machine learning and the possibility of data mining through EHRs to find population health trends and improve them.

The most basic use of HIT is to transition from paper charting to electronic charting. The transition was spurred by the belief that EHRs would help decrease medical errors and enhance care collaborations. To achieve high use, governmental push included redefining “meaningful use,” then financial incentives and later penalties for nonuse.

The concept of meaningful use is embedded within the ACA. Meaningful Use entails financial incentives for providers (professionals and hospitals) in their “meaningful use” of certified *electronic health records* (EHR) to improve patient care. Examples of Eligible Professional Core Objectives are: use of computerized physician order entry (CPOE) for medication, laboratory, and radiology; generating and transmitting permissible prescriptions electronically (eRx); recording specific demographics (preferred language, sex, race, ethnicity, date of birth); recording smoking status for patients 13 years old and older; use of clinical decision support to improve performance on high-priority health conditions; a provider who receives a patient from another setting of care or provider of care should perform medication reconciliation; a provider who transitions their patient to another setting of care or provider of care or refers their patient to another provider of care provides a summary of care record for each transition of care or referral.

In addition, to receive an incentive payment, providers are required to submit Clinical Quality Measure (CQM) data through the EHR that measure and track the quality of health care services. These include health outcomes, clinical processes, patient safety, efficient use of health care resources, care coordination, patient engagements, population and public health, and adherence to clinical guidelines.

The effect of EHR implementation on medical practice has been profound. The first impact has been a change in how physician–patient encounters are conducted. Over the past two decades, the length of the average ambulatory experience has decreased to less than 13 minutes. In parallel, rates of burnout in physicians have grown as EHR use has become commonplace. An analysis of time spent with patients versus completing EHR/bureaucratic tasks indicates that up to 50% of encounter time is used to complete those tasks, and most physicians chart 1 to 2 hours after the workday is over. No EHR seems to have significantly better satisfaction or less burnout than others. The trend of EHR adoption also coincided with an increased emphasis on patient satisfaction. However, patient satisfaction depends mainly on a higher percentage of gaze level from the physician. Some literature from 2000 to 2015 encourages physicians to multitask better to meet the need for patient eye contact and keep the human touch in the clinical encounter. However, there is a growing awareness of the transformation of the clinical encounter in the past few years and that burnout was reaching nationwide severe proportions. Physicians who have to continue/finish their charting at home have increased odds of burnout and HIT-related stress. Patient satisfaction tends to drop when there is a switch from paper charting to HER, potentially reflective of the change in human interaction level. Therefore, as a significant reform move, HIT has transformed medicine as we know it, with some positive and some very significant negative, unintended consequences. Some of these consequences can be mitigated with training to enhance documentation quality, readability, and clinical accuracy. Training can lead to fewer medical errors and increased efficiency in chart review and data retrieval; however effective trainings are few and far between, and on a national level, physicians still rate EHR as a major reason for burnout. This is especially true in primary care specialties, and job satisfaction is related to HER satisfaction in some cases. The impact of trainings and other HER improvement strategies on burnout range from about 5%. In psychiatry, specifically, HER has transformed and quasi-annihilated the therapy experience, though, for fairness, it is necessary to point out that the demise of psychotherapy administered by psychiatrists started with managed care, another wave of reform that preceded the HIT/HER implementation. Most depression treatment has turned to psychotropic prescribing in the past two decades with a concomitant decrease in psychotherapy. While one cannot pinpoint a single factor as responsible for decreasing psychotherapy rates, a plethora of factors, including the change in physical settings needed to implement HER, may have contributed, as well as workflow disruptions. Interestingly, a measure of dissatisfaction with HER is that patients consistently overestimate the amount spent by physicians on HER.

The experiment with HER is significant as HIT can further modify the medical experience, HER modifications focusing on higher-level cognitive tasks and improved team communication may help, and improved patient portal usage to help with health maintenance.

The next stages for HIT expansion are big data analysis and health outcomes optimization via data mining and patient-reported outcomes (PROs). From a systems perspective, the quasi-universal use of HER and the level of acceptability in patients makes it possible to use it for (1) PROs so that clinicians do not have to ask questions in session as much, (2) Diagnostic validation, and (3) Interface with applications and wearables outside of session. All these goals are still years away but are abundantly discussed as the next frontiers in HIT and the improvement of health care. The PCORI is an excellent resource to guide this field development effort. The Users’ Guide to Integrating Patient-Reported Outcomes in Electronic Health Records aims to outline a map of PRO-EHR integration across the planning, selection, and engagement areas.

In order to properly use PROs, careful selection of what outcomes to use has to occur first. The outcomes must be clinically meaningful, have some expected impact over the disease course or illness treatment decisions, or patient self-efficacy, and present a reasonable burden for patients regarding time and accessibility. For psychiatric illnesses, substance use disorders, mood symptoms, and medication adherence are obvious choices. Regardless of challenges, the potential for large-scale data collection and standardization is obvious with HER integration. This innovation will pave the way for effective population surveillance.

Second, patient engagement is crucial and may highlight socioeconomic and educational status disparities. While smartphone ownership is quasi-ubiquitous, technical literacy is still subject to socioeconomic and age disparities, with younger, wealthier individuals being more technology-savvy. Individuals with psychotic disorders and severe depression, catatonia, or mania may not fully engage in PRO collection or use and may need separate workflows; these challenges are specific to psychiatry and specifically to those working with populations with severe mental illness. Specifically, smartphone ownership and app usage are shown to be much less in individuals with psychotic disorders than those without, and this could be related to the nature of their illness, with paranoia and delusions centered around the information being collected, the effect of magnetic waves from the phone or wearable, and the way information will be used.

Third, the field currently lacks guidelines to support PRO meaningful interpretation. For example, patients logging their mood or filling out a mood questionnaire cannot get a personalized, treatment-driven interpretation of their symptoms. The information must be available to their clinician to be usable, which requires interoperability with EHR. Last, the liability of clinicians and health care systems of PRO-generated info is not tested yet. One can think of scenarios when PRO include mood deterioration or suicidal ideations preceding an adverse outcome such as a completed suicide. This area is unexplored yet, and there are no guidance measures to lead psychiatrists to use apps, wearables, or PRO portals from their institutions for patient care.

Accessing patients to their PRO and interpretation of information provided is a field of its own, currently undergoing extensive growth. The federal laws protecting patient access to their medical record should cover that, but again, this is an expanding area with no formal guidance. In order for the next HIT revolution and reform to occur, specifically in the context of having patients fill in PRO, several steps have to be formalized:

- The health system culture has to acknowledge the importance and usefulness of PRO and support the use of PROs.
- Health systems have to invest in PRO collection as a necessary means to help patients and clinicians improve population health one individual at a time.
- Training and efforts to promote this culture change, including cost and time requirements, must be provided. On a more psychiatry-specific and disease-specific level, a framework to build notification procedures and modalities and identify the appropriate recipients to receive notifications for PRO data will be needed (who will be on call for late evening patient digital alerts?). In certain situations, alert fatigue may become a theoretical possibility, as with personality disorders patients.

A Further EHR-HIT reform element is the allocation of wearables to monitor health outcomes when patients are in their natural environment. This is far from reality in psychiatry but is, like PROs above, being discussed and planned as the next step in patient-centered population improvement relying on real-time data. Areas of interest identified in order for this transition to be successful include “device type, communication interface, data transfer protocol, smartphone and/or PC integration, direct integration to open health platform, 3rd platform integration with open health platform, support for health care system/middleware connection, recorded health data types, integrated sensors, medical device certification, whether or not the user can access collected data, device developer access, and device availability on the market.” At this point, those measures are best suited for physical illnesses with well-defined physiologic markers that can be used to build machine learning algorithms, for example, heart rate, blood pressure, or blood sugar.

In conclusion, the issues involved in reforming health care are complex and transformational. They have the potential to change the way medical encounters are conducted.

Effective reform requires the expertise of a broad range of disciplines, from economics to ethics to basic public philosophy, and effects take decades to show. Therefore, psychiatrists must remain an integral part of the conversation as users of the system and as physician leaders and be ready with a clear vision and meaningful participation in the national health care dialogue.

56.3 The Role of the Hospital in the Care of Persons with Mental Illness

ERICA TAYLOR, M.D., M.P.H.

Throughout the 19th century and for the first half of the 20th century, public psychiatric hospitals (and some private ones as well) provided all the roles necessary to take care of psychiatric patients. The state hospital was the source for inpatient, outpatient, case management and outreach, and emergency services. If someone needed admission, a family member could simply transport him to the front door. With the shift from inpatient to community-based services that began in earnest in the mid-20th century, admission to, discharge from, and services within the psychiatric hospital became both more complex and more convoluted. Layer upon layer of agencies, services, and regulations facilitated and impeded the psychiatric hospital in its mission (Fig. 56.3–1).

The reasons for the evolution of this relationship between the psychiatric hospital and its prospective and actual patients are multifactorial. As Figure 56.3–1 illustrates, there are entities with overlapping but competing agendas at every turn. Fundamentally, there are two predominant factors that account for the contemporary, tortuous, labyrinthine interface between the psychiatric hospital and the community. First, the psychiatric hospital, in a manner quite distinct from the general hospital, plays two roles: clinical services and public safety, thus, the extensive interface between the psychiatric hospital and the criminal justice system (see Fig. 56.3–1). And second, psychiatry, more than any other field of medicine, has been inundated by gyrations of conflicting actions to decrease the cost of care and treatment, thus the barriers and alternatives to psychiatric hospital admission (see Fig. 56.3–1).

FIGURE 56.3–1. The psychiatric hospital in the context of the community.

The first one-and-one-half decades of the 21st century have not been kind to psychiatric hospitals. Virtually every state in the United States is experiencing a shortage of psychiatric beds. These shortages include acute care beds, intermediate and long-term care beds, and forensic beds. The effects of these bed shortages are increased waiting lists for state hospital beds, increased waiting lists for other psychiatric beds like general hospitals and Veterans Administration (VA) psychiatric beds, overcrowding in state hospitals, backups, and boarding in general hospital emergency departments (EDs), and premature discharges from acute care settings. These shortages have also meant a shift of persons with serious mental illness (SMI) behind locked doors from public hospitals to jails and prisons. These psychiatric bed closures come from all types of hospitals. Sixty-four percent of states have experienced declines in the number of general hospital specialty unit psychiatric beds, and 19 states have experienced a decline in the number of private psychiatric hospital beds. Nationwide, the number of state and county hospital beds declined by 86% (369,999 to 52,612) between 1969 and 2002; the number of VA medical center (VAMC) psychiatric beds declined by 84% (51,696 to

8,386) within the same time period. The inaccessibility of psychiatric beds is a regular feature in news stories and editorials, often with a link between that and a local or national tragedy.

Lengths of stay have plummeted. Between 1990 and 2010, the length of stay of hospitalizations for SMI in acute care settings decreased by 50% (from 14 days to 7 days). Private insurers represent a shrinkage percentage of payments for hospital services, especially for substance abuse services. About 50% of all payments for psychiatric inpatient services were from government programs; state governments' funding increased by 65% just between 2000 and 2001.

Hospital-based outpatient services grew by 78% (242,301 episodes to 1,104,300) between 1969 and 2002. In 2002, however, hospital-based outpatient services represented only 31% of all outpatient episodes of care for psychiatric disorders.

The shift of resources from hospital to nonhospital services is reflected by the changing distribution of expenditures by state mental health authorities (SMHAs). Inpatient services received 63% of the SMHA budget in 1981, 50% in 1993, 28% in 2004, and 23% in 2012. Although the overall inpatient percentage decreased, the proportion going to forensic patients increased to 33% of all state hospital expenditures.

While there has been a shift in public expenditures from inpatient to outpatient services, there has been an overall decrease in public expenditures for psychiatric treatment. In fiscal years 2010 and 2011, the biggest cuts were directed at state hospitals with 20 and 15 states, respectively, cutting state hospital funding. Less funding meant fewer individuals could be serviced in state hospitals, with 31 states decreasing the persons they admitted comparing 2007 to 2009.

At the same time, the demand for state hospital utilization increased in 18% of the states, in part because states were also making cuts in all manner of community-based services. Between fiscal years 2009 and 2011, 17 states had cuts in their overall state mental health expenditures by greater than 1%, with 5 of those states exceeding 20% (1 state approached 50%).

Marshaling scarce resources has led to synergies among various sectors within a state. In just more than 75% of the states, community-based programs (often at general hospitals) perform a gate-keeping function to state hospital entry. Some states (38%) require general hospital admission prior to a transfer to a state hospital. And in all but five states, there are assisted outpatient commitment (AOT) (involuntary outpatient commitment) laws on the books with an expectation these can be used to decrease both inpatient and overall mental health services costs.

The picture does not look optimistic, at least for the immediate future. About half of the states are reorganizing their state hospitals, including downsizing, reconfiguring, closing, and/or consolidating. Despite this, 11 states still have 6 or more state hospitals each. And a surprising number of states are building new state hospital buildings, but these generally replace one or more existing state hospitals and usually do not reflect an increase in beds (see Table 56.3–1). As more patients are admitted under forensic commitments, lengths of stay increase, and so does the unavailability of beds to others. In 2006, about 40% of patients found not guilty by reason of insanity had lengths of stay of 1 to 5 years, and about 38% had lengths of stay of greater than 5 years.

While the place of psychiatric hospitals as a tool in the resources box of treatment for mental illness is shrinking, the need is growing. On any given day in the fiscal year 2010, the number of noninstitutionalized individuals with an episode of serious psychological distress in the past was 3% of the population. In 2012, 4.1% of the adult U.S. population had an episode of SMI in the past year. The 12-month prevalence for schizophrenia in adults was 1.15%, while it was 3.5% for post-traumatic stress disorder (PTSD) (one-third of these classified as severe), 9.1% for any personality disorder, and 18.1% for anxiety disorder (23% of these classified as severe). The mismatch between need and services is no better represented than by the fact that in 2008 over 40% of adults in the United States with an SMI did not receive any treatment for a mental health problem. Of those that did, 7.5% had an inpatient, and 40.5% had an outpatient episode of care.

The state of hospital psychiatry raises questions about how it came to play the roles it does. What were the historical influences that brought the psychiatric hospital to where it is, and what keeps it there? How does the psychiatric hospital (this term will include general hospital psychiatry units) fulfill its current role? And what should be the roles of psychiatric hospitals in the future?

THE HISTORICAL EVOLUTION OF THE ROLE OF THE HOSPITAL

Prior to the 19th century, the care of insane persons was custodial in nature, took place largely in almshouses, and was predominantly a local endeavor. State care, in the beginning, meant an institution established, built, and managed by the state but whose operation was not funded by the state. Payers were, in descending order of priority, the patient, the family, and the county. The earliest public facilities—in Williamsburg, Virginia, and Columbia, South Carolina—functioned in this manner. The state taking responsibility for all insane persons and performing its responsibility through state-managed and funded hospitals began with Worcester State Hospital in 1833.

Before there were any more than a few public hospitals, there was already a well-established group of private psychiatric hospitals. Three of these began as parts of general medical hospitals: The Institute of the Pennsylvania Hospital, Bloomingdale Hospital (New York), and McLean Hospital (Massachusetts). Three more were freestanding institutions: Butler Hospital (Rhode Island); Brattleboro Retreat, which began as the Vermont Asylum for the Insane; and the Hartford Retreat, which subsequently was renamed the Institute of Living (Connecticut). Two of the hospitals began under the aegis of religious organizations: The Friends Asylum (Pennsylvania) was initiated by a Quarterly Meeting of the Philadelphia Society of Friends, and the Mount Hope Institution (Maryland) was a Catholic hospital that began as the Mount Saint Vincent Hospital.

Of these larger private facilities, all but one preceded the state's first public hospital, sometimes by more than 50 years. The private hospitals helped the state to meet its obligations to the insane poor by admitting "public" patients. Payments were made by the state to the private facility, and some treatment was given without charge. Thus, the states' purchase of beds from the private sector was not a novel concept of the late 20th century but is actually how U.S. hospital psychiatry began.

Many public and some private hospitals throughout the country were built under a design put forth by Thomas Kirkbride, a founding member of the American Psychiatric Association (APA). In his book, *On the Construction, Organization, and General Arrangements of Hospitals for the Insane*, Kirkbride prescribed every aspect of hospital construction and operation. His prototype hospital, variations of which can still be seen across the United States (but are fast being torn down), is shown in Figures 56.3–2 and 56.3–3. Noteworthy among his recommendations is that a 250-bed hospital would have 16 wards, with about 15 patients per ward.

Additional Facilities Opened Since 2005.

California: Coalinga State Hospital—opened Sep 2005, beds 1,260.

Connecticut: Silver Hill Hospital, Chronic Pain and Recovery Center Program—opened 2012 (no bed count).

Silver Hill Hospital, Eating Disorder Program for Adults—opened 2015 (no bed count).

Indiana: NeuroDiagnostic Institute—opened March 2019, beds 159.

Texas: University Behavior Health Denton—opened 2005, bed 104.

By the 1880s, most psychiatrists agreed that “insane patients can best be managed away from their own homes.” Parsons, an alienist of the era, opined, “well-equipped and well-managed asylums for the insane are among the most important of the outgrowths of modern civilization and benevolence.” By the end of the 19th century, it was clear that private facilities were for the wealthier, more genteel class of citizens, who were able to pay fees and were provided remarkably comfortable accommodations. Public hospitals were entities of the state, county, or municipal governments that served not only the poor but also the middle class, given that the latter could not afford private hospitals.

A major difference between the public and private facilities is that public institutions sought to lower their censuses as state hospital populations grew and patients had progressively longer lengths of stay, whereas private facilities sought patients to maximize their occupancy rates. A fundamental criticism of private facilities was pointed out by Parsons: “It is not for the interest of the proprietor of a private asylum to cure his patients, and hence they may not make an honest effort to promote their cure.” Much of what many consider to be modern developments in hospital psychiatry were well under way before the end of the 19th century: Oversight of private hospitals by state boards, advertising by private hospitals, involuntary admissions to private hospitals, more perks for higher fees, and the “dumping” of patients from the private to the public sector.

Work and recreation were both seen as important to the mental health of patients in the 19th century. Generally, the public hospitals did better with the former, and the private ones with the latter. Recovery, employment, and wellness are not novel ideas of contemporary hospital psychiatry. Each was endorsed more than 150 years ago in both public and private hospitals.

Nor is evidence-based psychiatry a new thought. Andrews articulated in 1887 that “the unparalleled progress in neurology, cerebral anatomy, physiology, pathology, and localization of function has enlarged the horizon of our knowledge of disease and of the action of causes.” This progress, he said, “furnished a scientific and positive basis for treatment in many cases of insanity which before was unattainable.” Inpatient treatments near the end of the 19th century included such modalities as electricity, massage, oophorectomy, enforced rest, hydrotherapy, and physical training.

Changes in hospital psychiatry over the first half of the 20th century were dramatic. Psychoanalysis was introduced to the inpatient setting in the 1920s and somatic treatments such as insulin coma, Metrazol shock, and electroconvulsive therapy in the 1930s. In the 1940s, attention was focused on developing milieu therapy, whereas in the 1950s, the introduction of the first antipsychotic medication, chlorpromazine, fundamentally altered inpatient psychiatry.

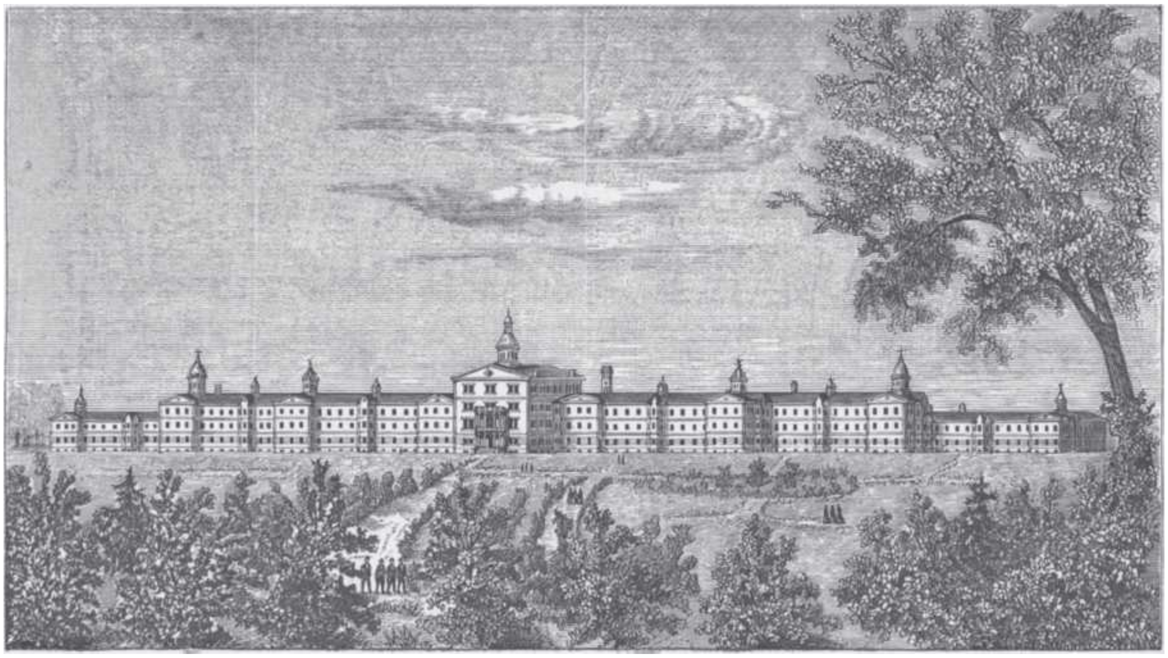

FIGURE 56.3–2. Exterior of hospital prototype designed by Thomas Kirkbride. (From Kirkbride TS. *On the Construction, Organization, and General Arrangements of Hospital for the Insane*. J.B. Lippincott; 1880.)

The mid-1950s began the shift from hospital-based to nonhospital-based care and treatment of persons with mental illness, a movement retrospectively labeled “deinstitutionalization” but perhaps better termed “dehospitalization.” General hospital psychiatry and day hospitals became major loci of care and treatment, and the role of the psychopathic hospital expanded. Units in general hospitals were not always welcomed by hospital medical staff, who were concerned that psychiatric patients, whom the physician thought would overwhelmingly be noisy, destructive, violent, or suicidal, would disrupt the general hospital.

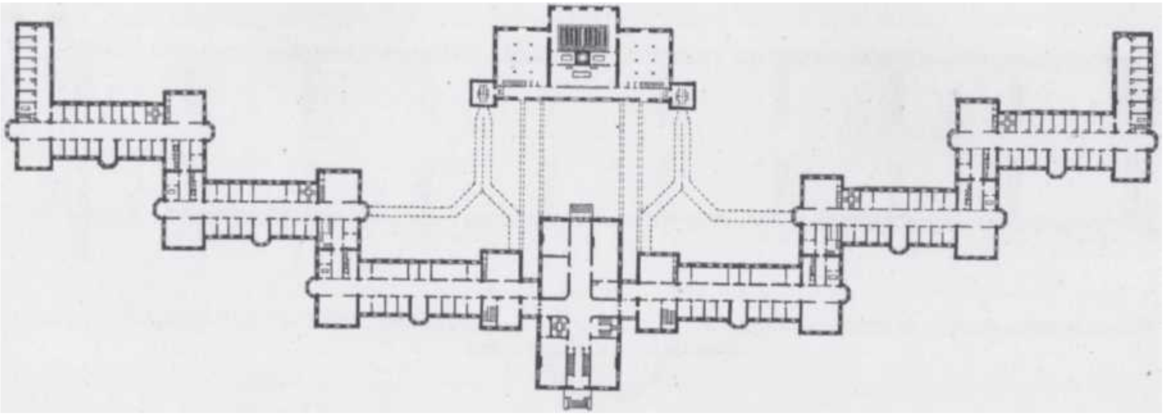

FIGURE 56.3–3. Interior of hospital prototype designed by Thomas Kirkbride. (Kirkbride TS. *On the Construction, Organization, and General Arrangements of Hospital for the Insane*. J.B. Lippincott; 1880.)

The darkest era in U.S. hospital psychiatry was in the 1940s, a time when the care of persons with mental illness was described as a national disgrace. Attempts were made to improve inpatient treatment through the promulgation of principles and standards, such as those put forward by the Division of Mental Hygiene of the U.S. Public Health Service, the National Committee for Mental Hygiene, and the APA's Committee on Psychiatric Standards and Policies. These probably had less effect than exposés such as Mary Jane Ward's *The Snake Pit*, a fictionalized first-person account of life in a state hospital.

Whereas the public sector was overburdened and overrun, by 1950, the private sector was also facing financial difficulties. The Medical Director of McLean Hospital stated at the 1950 APA Institute, "The time when you could run a private hospital as a hospital and make money has gone. Operating expenses have so increased that it is almost impossible to collect the cost from our patients."

In the 1960s, as health insurance for hospitalization expanded to include psychiatric treatment, psychiatric hospital treatment outside of state hospitals became more available. Misuse of insurance for hospitalization for mental illness was quickly recognized. To remedy the manipulation of hospital benefits, interventions were introduced: Peer review, reimbursement for partial hospitalization, and reimbursement for other alternatives to inpatient treatment. “Dumping” and “cost-shifting” emerged as part of the everyday life of inpatient psychiatry.

In the 1970s, states were contemplating phasing out state hospitals. General hospital psychiatric units were becoming more of a presence. The expanding role of general hospital psychiatry drew caution from some who warned workers in general hospitals to be watchful of efforts to convert general hospital psychiatric units into mini-state hospitals. Declining numbers of individuals willing or able to pay for private hospital treatment and more available third-party coverage led private hospitals to admit patients of different socioeconomic classes and ethnic backgrounds and to keep all patients for shorter lengths of stay.

In the 1980s, there was a remarkable growth in private sector hospital beds. Private corporations were rushing to build psychiatric hospitals as less regulation, lower overhead, and greater latitude in insurance reimbursement meant there were huge profits to be made in the “psychiatric hospital industry.” For-profit psychiatry grew, but with it came a new set of problems. For-profit hospitals were the least likely to treat the most functionally disabled; would treat few if any patients who could not pay for treatment; usually had poorer staff-to-patient ratios than nonprofit hospitals; failed to provide education and training; failed to contribute adequately to research, and overall provided a lower quality of care. These hospitals tended to be totally disengaged from the communities in which they were located; they paid higher salaries and thus hired away graduating residents from academic and public sector positions.

The heyday of for-profit hospitals (most private psychiatric hospitals) did not last long. Throughout the 1990s, the total and the average number of beds per private hospital decreased, as did the average length of stay. Between 1992 and 1998, private psychiatric hospital beds declined by 23%. For-profit companies had built “chains” of hospitals so rapidly that there quickly came to be too many private psychiatric beds, and hospital chains began experiencing major financial losses. Lawsuits against the chains for unscrupulous practices such as recruitment of patients and manipulative billing practices were settled in the hundreds of millions of dollars.

The 1990s also witnessed the privatization of public mental health services. Medicaid, Medicare, and state funds were directed to the private sector to greater degrees during the 1980s and 1990s. States assisted freestanding private hospitals in obtaining waivers of the Institution for

Mental Disorders (IMD) rule (see later discussion). A greater reliance on the private system for those formerly treated in the public system created many unintended consequences that varied state by state, including inpatient treatment further from one's community, less continuity of inpatient treatment, new patterns of recidivism, and certain patients being blacklisted at some hospitals.

In 2001, 37% of general hospitals had psychiatric inpatient care. This percentage is higher than those with a psychiatric emergency, consultation-liaison (C-L), or even outpatient services. Hospital psychiatry in the United States continued to be a *business*. However, in the business of psychiatry, nonprofit psychiatric care providers compared favorably with for-profit providers.

It is interesting to note how the practice of hospital psychiatry appears to have shifted in response to shorter lengths of stay. A study at McLean Hospital in 2002 that compared inpatient antipsychotic medication use in 1989, 1993, and 1998 showed the chlorpromazine-equivalent final total dose of all antipsychotic medications used at discharge in 1998 was 29.3% greater than in 1993 and 46.1% greater than in 1989. The average time from admission to first antipsychotic dose decreased dramatically from 6.8 days in 1989 to 1.5 days in 1993 and .9 days in 1998. Two or more antipsychotic medications were used during 20% of inpatient days in 1998, compared to 5.7% days in 1993 and 1.7% in 1989. Pressures to discharge patients reduced not only the length of treatment but also the content of treatment.

In the first decade of the 2000s, the prospects for the private psychiatric hospital and for general hospital psychiatric units did not look good. Although overall health care spending increased by 15.7% between 1992 and 1999, mental health and substance abuse spending decreased by 17.4%. Behavioral health care spending went from 7.2% of total private health insurance spending to 5.1% over this same time period. Reimbursement rates fell such that they often did not even meet the total costs of care and treatment. While reimbursement rates fell, costs to deliver treatment increased.

Private hospitals were offering fewer services. Those hospitals offering partial programs decreased from 82.5% to 66.7%, and those offering outpatient services dropped from 64.2 to 49.2% between 2000 and 2001. At the same time, oversight increased. The Office of the Inspector General (OIG) of the Department of Health and Human Services, the Joint

Commission on Accreditation of Healthcare Organizations, and the Center for Medicare and Medicaid Services all stepped up investigations of hospitals. Medicaid's progressive decrease in disproportionate share payments (DSHs) to public mental hospitals is taxing some states' ability to operate their public system at its pre-2000 scale.

The landscape of U.S. inpatient psychiatry became so rough that well-established private hospitals closed or moved. Those in the former category include Taylor Manor and Chestnut Lodge in Maryland. In the latter category, the best known is the Menninger Clinic, formerly of Topeka, Kansas, and now in Houston, Texas. In the public sector, state hospitals, well established since the 19th century, began reinventing themselves, usually by the consolidation of multiple public hospitals and by new construction such as Worcester State Hospital (Massachusetts), Oregon State Hospital, and Western State Hospital (Virginia). Furthermore, the need to serve and contain persons with mental illness and histories of sexually problematic behaviors is diverting resources from the treatment of psychiatric disorders. California built a 1,500-bed facility for forensically committed individuals—mostly sexually violent predators—representing the first new California facility in more than 50 years. Even older adult individuals with such histories can often not be discharged from the public psychiatric hospital as federal law prohibits nursing homes from admitting persons who are classified as the highest level of sex offenders.

As components of psychiatric services in the second decade of the 21st century, psychiatry hospitals are shrinking, growing, being torn down, and being newly built all at the same time. As hospitals are unable to meet the needs of the population requiring inpatient level of care, local police have become the triage agents for persons with serious mental illness in the streets; jails and prisons are unofficial replacement facilities for state hospitals, and mental health courts provide more case management than anything else. One potential positive note is the growing number of new public psychiatric hospitals built with the hope that the building's design will facilitate patients' recovery (see Table 56.3–1). It is well worth remembering, however, the observation made in the wake of newly constructed community mental health centers (CMHCs) with inpatient units in the 1970s: the latest in "psychoarchitecture" and design elements do not result in behavioral remediation since clinical improvement does not result simply from changing bricks, mortar, and furniture. That being said, newly built hospitals, most of which have had significant problems with translating programmatic and life safety design concepts into actual hospital structures, have brought more pleasant surroundings, in an overall safer environment, with more available space for in- and outdoor programming (see Figs. 56.3–4 and 56.3–5). These figures are presented as an example and not as a model.

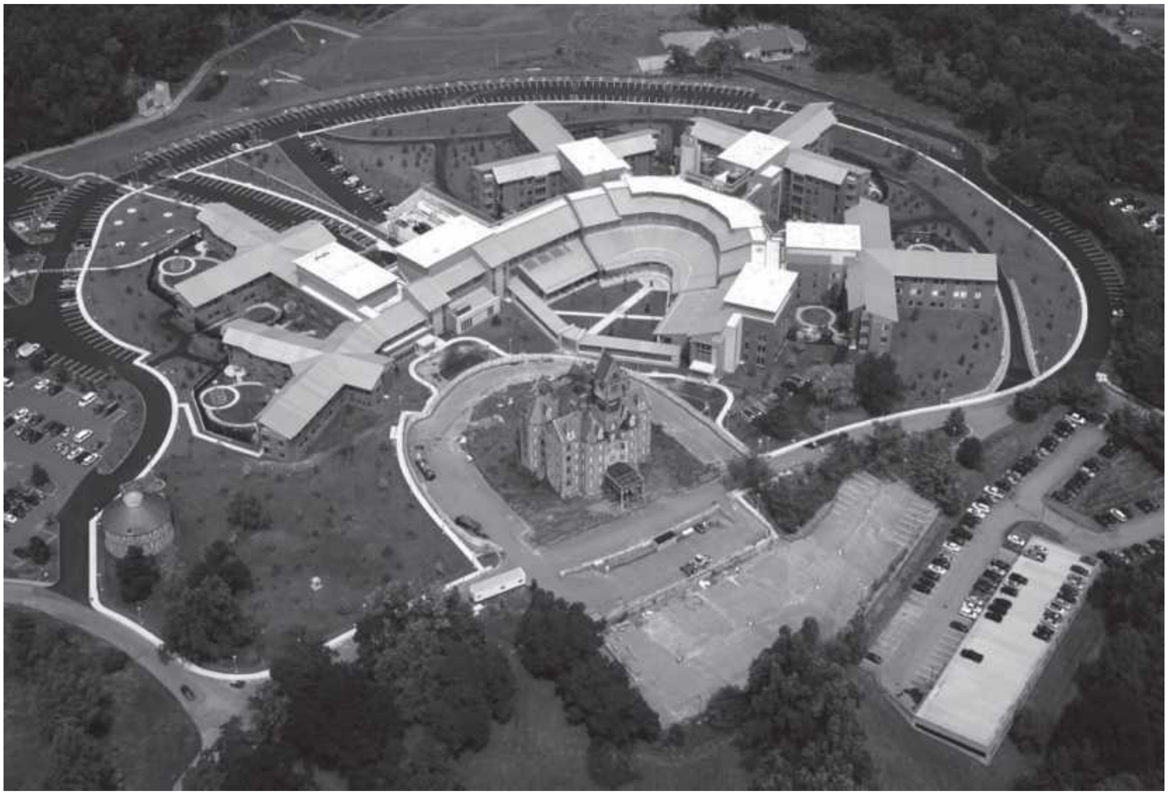

FIGURE 56.3–4. Worcester Recovery Center and Hospital (WRCH). Exterior view.

Available psychiatric beds in general and private hospitals appear to be made inaccessible to patients by insurance providers because limiting admission to hospitals with which they have negotiated rates is one means to control cost. As reimbursement rates drop below the actual expenditures of the general hospital, these hospitals limit the third-party payers with which they will contract or further reduce or eliminate psychiatric beds, exacerbating the bed shortage.

Public psychiatric beds are highly disproportionately occupied by forensically committed patients. This makes beds for civil admissions less available, and patients are stuck in general or private psychiatric hospital beds, which in turn delays the movement of psychiatric patients needing admission out of the ED. Waiting time in an ED can be up to 1 month for a psychiatric bed, or the patient is prematurely discharged from the ED, sometimes with lethal consequences.

Despite ascriptions of causality for the current state of hospital psychiatry to malevolence, malfeasance, and malversation, it would seem more accurate to see the role of the psychiatric hospital in the second decade of the 21st century as still the result of a basic tension between clinical benefit, social control functions, and parsing out of costs. Each governmental level and each government agency wants another one to fund the treatment of mental illnesses.

Despite all of these uncertainties, there is no indication that psychiatric hospitals will cease to play some role in the future. The remainder of this section focuses first on defining the role of the hospital and then on implementing that role.

DEFINING THE ROLE OF THE PSYCHIATRIC HOSPITAL

Clinical Rationale

The clinical rationale for the role of the psychiatric hospital was well established by the mid-18th century. Edward Jarvis, a nonpsychiatrist physician, well enmeshed in the psychiatric care of his era, stated it as well as anyone. First, Jarvis discussed his thoughts on “diseases of the mind”:

> Maladies of the mind, like those of the body, require that the causes that produced them shall cease to act upon them. Unfortunately the diseases of the mind frequently find their origin in the circumstances and associations of home, in the cares and anxieties of business, in the relations of neighborhood, in the affairs of the town, in the movements of religious, political or other associations, in the habits of indulgences which are practiced. Or when the diseases are once established, they may be kept up by some of these. Moreover, the natural perceptions and moral sensibilities being disordered, the scenes, circumstances, and the persons, which are usually agreeable and favorable, in health, become objects of aversion and sources of irritation and keep the disorder alive. (Jarvis E. *Address Delivered at the Laying of the Corner Stone of the Insane Hospital, at Northampton, Massachusetts.* J&L Metcalf; 1856.)

Then Jarvis provided his thinking on why hospitals were needed to treat persons with these diseases:

> As the lunatic cannot be separated from these, while in his own house, he must go from them and generally among strangers. It is needful that the mentally disordered not only go away from home, but be placed where all the circumstances and associations are different from those to which he has been recently accustomed, and where all the influences that may reach him, can be controlled and modified, so that none but such as are favorable may affect him. They will be found in the hospital [where] the officers and the attendants are selected on account of their peculiar fitness for their work. They have the high intelligence, the scientific knowledge, and the moral endowments of gentleness, and firmness, and sympathy that are required, and they know how to occupy the diseased mind and lead it from its morbid fancies, and fix it upon cheerful and satisfactory subjects. (Jarvis E. *Address Delivered at the Laying of the Corner Stone of the Insane Hospital, at Northampton, Massachusetts.* J&L Metcalf; 1856.)

Jarvis provided a quite optimistic prognosis if his recommendations were followed, but one quite consistent with those of his professional colleagues: “If insane persons are allowed to enjoy the means of healing in the early stages of their disorder, within one year after it appears, about

75 to 90 percent, can be restored to health.” Furthermore, he argued for prompt hospitalization with the onset of symptoms:

> But in this class of maladies, time makes rapid havoc and diminishes the chances of cure. If the means of healing are not tried within the first year, the ratio of cures is reduced perhaps a half in the second and still more in the third year, and when five years of neglect shall have elapsed, the hope of restoration is reduced to a mere accident, which no human skill can promise to accomplish. (Jarvis E. *Address Delivered at the Laying of the Corner Stone of the Insane Hospital, at Northampton, Massachusetts.* J&L Metcalf; 1856.)

By the mid-19th century, it was also clear to those who treated persons with insanity that the hospital had much to offer those in need of acute treatment due to advances in the field. Samuel Woodward, the first president of the APA, noted the following in 1846:

> The abandonment of depletion, external irritants, drastic purges, and starvation, and the substitution of baths, narcotics, tonics, and generous diet, is not less to be appreciated in the improved condition of the insane, than the change from manacles, chains, by-locks and confining chairs, to the present system of kindness, confidence, social intercourse, labor, religious teaching, and freedom from restraint. In this age of improvement, no class of mankind have felt its influence more favorably than the insane. (Woodward SB. Observations on the medical treatment of insanity. *Am J Psychiatry.* 1850;7(1):1–34. doi: 10.1176/ajp.7.1.1.)

Hospital treatment continued to improve in the mid-19th century. Charles Nichols, superintendent of the Government Hospital for the Insane (St. Elizabeth’s), commented as follows in the 1870s: “Much less mechanical restraint, and much less seclusion are now used in our institutions for the insane than were formerly resorted to in them. . . . I trust that we shall be able to still further reduce the proportion of cases in which restraint will be deemed advisable.”

The role the physician could play in the hospital was also clear by the mid-19th century. Luther Bell, superintendent of the McLean Asylum, indicated in 1849:

> Domiciliated with our patients, ready at all hours, by day or night, to watch the effect of our prescriptions, sure of their being fairly and fully carried into effect, without hazard of the interference of timid friends or unfaithful nurses; obliged to make no disguise, no prescription for form or appearance sake, it is in our power to follow out the best convictions of our judgment, uninfluenced by aught extraneous to the object desired. (Bell LV. On a Form of Disease resembling some advanced stages of mania and fever, but so contradistinguished from any ordinarily observed or described combination of symptoms, as to render it probable that it may be an overlooked and hitherto unrecorded malady. *Am J psychiatry.* 1849;6(2):97–127. doi: 10.1176/ajp.6.2.97.)

That the psychiatric hospital played a far greater role than just treating acutely ill insane persons and restoring them to health was quite clear by that time. William Awl, superintendent of the Ohio Lunatic Asylum in Columbus, wrote in 1849:

> More effort and skill is often demanded, to better the condition and make some improvement in the shattered intellects of those who are deemed hopeless, than to effect recoveries. . . We must never permit ourselves to lose sight of humanity, but always remember the importance of the institution to all classes, and the advantages which may be secured to those whom we are obliged to regard as incurable.

Thomas Kirkbride expanded on this note in 1864, indicating the importance of the safety function played by the hospital:

> Owing to various causes, but especially to a neglect of treatment in the early stages of the disease, there are a large number of the insane, in every community, whose chances of restoration are slight, but whose comfort and happiness are promoted, and their protection from ill treatment secured by a residence in these institutions, where they are under circumstances which give them the best chance for permanent improvement. To provide for this numerous class is another important object, attained by the establishment of such hospitals. Next to these come the protection of the community and the relief of private families.

These roles quickly became compromised by the services being overwhelmed by the number of patients needing to be served. By 1890, W. W. Godding, the APA's seventeenth president, was observing:

> The overcrowding goes on, cots are brought out at night and laid down on the corridor floors, at first one or two in nooks and alcoves that seem quite designed for this sort of thing, but the business grows, the special adaptation of recesses and alcoves becomes less apparent as the line of beds side by side stretches in lengthening vista down the hall. And still the floors fill up until one, two, three hundred are thus nightly not accommodated but provided for. From ground floor to attic your hospital, spread with its white beds seems a very bivouac of lunatics . . . Day by day, year after year, I have seen the individualized treatment of special cases swamped by the rising tide of indiscriminate lunacy pouring through the wards, filling every crevice, rising higher and higher until gradually most distinctions and landmarks have been blotted out. (Godding WW. Aspects and outlook of insanity in America. *Am J Psychiatry.* 1890;47(1):1–16.)

These trends persisted, such that by 1954 Kenneth Appel, the eighty-second president of the APA, echoed Godding:

> There is overcrowding 20–30% in 70% of…hospitals, and 50% overcrowding in 8% of the hospitals. Hospitals are 40% understaffed in physicians; 15,000 more psychiatrists are needed; 37,000 patients in 29 hospitals have no psychiatrists, and 2,000 patients are in 5 hospitals which do not employ a full-time physician. (Appel KE. President's page. *Am J Psychiatry.* 1954;110(11):859–864. https://doi.org/10.1176/ajp.110.11.859)

Four years later, Harry Solomon, director of the Boston Psychopathic Hospital, proclaimed:

> After 114 years of effort, in this year 1958, rarely has a state hospital an adequate staff as measured against the minimum standards set by our Association . . . I believe therefore that our large mental hospitals should be liquidated as rapidly as can be done in an orderly and progressive fashion.

Clinical concerns fueled the changing role of the hospital and the changing role of various classes of psychiatric hospitals (state, county, private, general hospital), but clinical concerns were never separate from fiscal concerns. It has never been clear which has been the predominant concern, but there is ample evidence accumulated over the last 150 years that economic considerations have been of no less importance than clinical considerations in defining the role of the hospital.

Social Control Rationale

Every state has statutes that govern the admission of persons with mental illness, over their objection, to hospitals within their state; the involuntary continued hospitalization of these individuals should they want to leave; the commitment of persons who have been charged with a crime and there is a question of their competency to stand trial and/or their criminal responsibility; and the transfer of inmates from jail and prisons to hospitals. Every state sets forth criteria under which an individual can be held on emergency detention and then civilly committed, and these criteria are uniformly danger to self, danger to others, and some variant of gravely disabled. The statutes for civil commitment are generally uniformly applied across hospital types, while forensic commitments are to government-run hospitals or in a few states to nongovernment hospitals with contracts with the state to provide such services.

In no other field of medicine could a competent person be admitted to a hospital over his objection. This occurs only in psychiatry and is the component of psychiatry that is social control. This social control function is the most fractious aspect of hospital psychiatry. It is this aspect of psychiatric hospitals that has been the brunt of antipsychiatry movements, whether they originate with psychiatrists themselves, for example, Thomas Szasz, R.D. Laing; religious groups; or individuals who label themselves “consumer survivors.”

So engulfing had the social control function of the psychiatric hospital become that until the early 1980s, simply being an involuntary patient at a psychiatric hospital meant one could be involuntarily medicated. The argument was a simple one: what was the purpose of holding a person in a hospital against his will if you could not treat him? This changed when, through litigation, the point was made that commitment is based on dangerousness, while the right to refuse treatment is based on competency (see, e.g., *Rogers v. Commissioner of Mental Health*, 390 Mass.489, 458 N.E.2d 308 [1982]).

The objection to the social control function of the hospital is hardly new. One-hundred and seventy-five years ago, Elizabeth Stone protested her admission to the McLean Asylum; 150 years ago, Elizabeth Packard made a career out of her protestations; and 70 years ago, actress Frances Farmer tried to rally the nation to support her self-proclaimed unjust involuntary admissions and treatment.

This week, in every state in the United States, there are individuals in various stages of civil and criminal commitment. There are also individuals being medicated over their objections. And what some believe is a glorious evolutionary step forward in mental health services and others think is a malevolent regression, a progressively larger percentage of involuntary treatment is taking place outside of hospitals, through AOT, mental health courts, conditional release, representative payeeships, leveraged housing, and probation.

So entrenched have these competing interests of social control versus autonomy become that each has its own set of slogans. Those in favor of treatment over objection in a defined set of circumstances talk about “rotting with your rights on.” Those in favor of free choice, no matter what the circumstances, chant: “Nothing about us without us.”

There is one area where both sides together object to the use of the psychiatric hospital as a social control agent—for individuals who do not meet the criteria for having a mental illness, or whose danger is not on the basis of a mental illness, or who are stuck in a hospital because they have no place to go—yet are committed to the psychiatric hospital. All states have their population of individuals who are there because their psychopathic behaviors land them in hospitals; individuals whose high-profile crimes make them “political prisoners,” and individuals whose dangerous sexual behaviors means they must be locked up somewhere. The latter situation is the basis for the Supreme Court decision in Kansas v. Hendricks (see Table 56.3–2).

It is perhaps the irony of the social control function of psychiatric hospitals that law enforcement cannot get individuals into hospitals who need to be there because district attorneys, forensic review boards, families, and victims fight to keep individuals in psychiatric hospitals who do not need to be there. The social control function is highly susceptible to stigma and prejudice.

Fiscal Rationale

In 1912, there was a debate in Congress on a government health insurance program. President Franklin Roosevelt almost established a federal health plan as part of the 1935 Social Security Act. Presidents Harry Truman and John Kennedy had health care proposals before Medicare and Medicaid passed during President Lyndon Johnson's term in office. However, before all that, President Franklin Pierce played a major role in the early eschewal of federal responsibility for the health care of persons with mental illness.

The individual most responsible for bringing the issue to President Pierce's desk was Dorothea Dix, a well-known reformer. On June 23, 1848, Dix delivered a Memorial Lecture to the U.S. Congress. Dix's subjects, as stated in her address, were as follows: "Allowing at the present time 22,000,000 inhabitants in the United States and supposing only one in every thousand to be insane or idiotic, we have then 22,000 to take charge of." She described the state they were in:

> a majority of whom are in needy or necessitous circumstances . . . destitute of appropriate care and protection . . . bound with galling chains, bowed beneath fetters and heavy iron balls, attached to drag chains, lacerated with ropes, scourged with rods, and terrified beneath storms of profane execrations and cruel blows . . . abandoned to the most loathsome necessities, or subject to the vilest and most outrageous violations.

Dix's remedy was hospitals: "No disease is more manageable or more easily cured than insanity; but to this end special appliances are necessary, which cannot be had in private families, nor in every town and city; hence the necessity for hospitals." Dix appealed to the legislators' sense of doing what is right: "Humanity requires that every insane person should receive the care appropriate to his condition." She articulated the social control function of the hospital by spelling out the civil and social obligation to consult and secure the public welfare: "First, in affording protection against the frequently manifested dangerous propensities of the insane." Furthermore, she made a powerful economic argument, indicating the insane and the community at large would benefit by "assuring seasonable and skillful remedial care, procuring their restoration to usefulness as citizens of the republic, and as members of communities."

Edward Jarvis best articulated the 19th-century position on the cost of care versus the cost of treatment that was fundamental to Dix's campaign:

> A man of twenty years of age, if sane, has an average life of 39.48 years, while if insane he has but an average life of 21.31 years if not restored to health. The average time for restoring to health the insane who apply for treatment upon the early symptoms of disease is twenty-six weeks. At $4 per week, which was the average cost in the three State Lunatic Asylums in Massachusetts for the past year, this amounts to $104, to which is added $30 for each patient, for the cost of rent or interest on the value of the hospital, etc., for six months, making an average cost of $134 for restoration to health. If not restored to health, the family or State must be at an expense of $156 a year for 21.31 years, and must also lose the patient's earnings for the 39.48 years which he would have made if well. The cost of the patient's support is estimated at $2,121, while the loss of his future labor, if he becomes insane at twenty years of age, is estimated at $2,665.37, making a total loss of $4,786.37 if not cured; while, if cured in the average time of twenty-six weeks at a cost of $134, there will be a gain to the family or to the State of $4,652. (Jarvis E. Treatment of insanity. In: Mann EC, ed. *A Manual of Psychological Medicine and Allied Nervous Diseases.* P. Blakiston, Son & Co; 1883.)

Dix lobbied for her land grants bill through four presidential administrations. The bill was passed by both houses of Congress during Franklin Pierce's term. However, Pierce vetoed the bill. In his Veto Message on May 3, 1854, first, he laid out the issues as he saw them:

> It cannot be questioned that if Congress has power to make provision for the indigent insane without the limits of the District it has the same power to provide for the indigent who are not insane, and thus to transfer to the Federal Government the charge of all the poor in all the States. It has the same power to provide hospitals and other local establishments for the care and cure of every species of human infirmity . . . The whole field of public beneficence is thrown open to the care and culture of the Federal Government.

Later in his Message, he explained the basis for his veto:

> If the several States, many of which have already laid the foundation of munificent establishments of local beneficence, and nearly all of which are proceeding to establish them, shall be led to suppose, as, should this bill become a law, they will be, that Congress is to make provisions for such objects, the fountains of charity will be dried up at home, and the several States, instead of bestowing their own means on the social wants of their own people, may themselves, through the strong temptation which appeals to states as to individuals, become humble supplicants for the bounty of the Federal Government.

From the veto by President Pierce into the early decades of the 20th century, the federal government was basically disinterested in the psychiatric and substance abuse populations. It eventually turned to the issues around the treatment of this population due to concerns about drug addiction. In 1914, the Harrison Narcotics Act allocated funds to study drug use. Subsequently, the Narcotics Division within the U.S. Public Health Service was created. It was renamed 2 years later the Division of Mental Health. In 1996, the federal government focused on mental illness with the passage of the National Mental Health Act, which established the National Institute of Mental Health (NIMH).

In 1989, the Omnibus Budget Reconciliation Act (OBRA) required the secretary of the Department of Health and Human Services to conduct a study of the IMD exclusion. The IMD exclusion dated from the 1950 Social Security Act Amendments, in which payments on behalf of those in IMDs were excluded from old-age assistance. This exclusion continued unchanged until the enactment of Medicaid under the Social Security Act Amendments of 1965. For the first time, states could use Federal Financial Participation (FFP) for a population in IMDs—in this case, those 65 years of age or older. States could bill the federal government to help pay for the treatment in psychiatric hospitals of patients who were older than the age of 65 years. Other populations were not included, but Congress did expand FFP for services to persons with mental illness in general hospitals.

The 1965 changes to the IMD exclusion began to allow states to shift the cost of mental illness expenditures to the federal government. In a state hospital, the state bears 100% of the cost of care and treatment. The state cannot bill Medicaid. In any facility that is eligible for Medicaid reimbursement, each state pays considerably less than 100%, according to the FFP formula: Nonfederal percentage = 45% × (per capita state income) ÷ (per capita national income). Historically the range of federal participation has been between 50% and 83%—thus the fiscal incentive to move patients out of state hospitals.

An IMD is a facility with more than 16 beds. In addition, any one of the following defines an IMD: (1) the facility is licensed as a psychiatric facility, (2) the facility is accredited as a psychiatric facility, (3) the facility is under the jurisdiction of the SMHA, (4) the facility specializes in providing psychiatric/psychological care and treatment, or (5) the current need for institutionalization for more than 50% of all of the patients/residents in the facility results from mental diseases.

In 1971, Congress expanded Medicaid to include coverage of services rendered in intermediate care facilities (ICFs). In 1972, Congress expanded FFP for inpatient psychiatric treatment in IMDs to individuals younger than 21 years of age so that now those younger than 21 and older than 65 years of age are eligible.

The IMD exclusion sets up a tension between the states and the federal government, each wanting to lower its share of the costs for psychiatric hospital treatment. Between 1972 and 1988, the federal government was busy with evaluating the proper application of the IMD exclusion by the states, disallowing certain states' practices, and defending itself in court. This culminated in the 1985 U.S. Supreme Court decision in *State of Connecticut Department of Income Maintenance v. Heckler,* in which the Court unanimously found for the federal government, indicating that a hospital, a skilled nursing facility (SNF), or an ICF could be an IMD.

Thus, the IMD exclusion profoundly affects the role of the psychiatric hospital and the distribution of patients across types of hospitals. States would rather have persons with mental illness in community residential settings than in state hospitals and in general hospitals rather than state hospitals. In both situations, the former means Medicaid payments; the latter means no Medicaid reimbursement.

No matter what the sector or who the payer, however, in the last quarter of the 20th century, inpatient psychiatric treatment was getting more and more costly—hence the rise of managed care. Starting in the 1970s and continuing through the early 1980s, the principal methods for cost containment were actuarial manipulations designed to manage benefits. There was little regard for the effect these changes in benefits had on the indirect costs borne by beneficiaries, employers, and/or the community. Changes were made without consideration of their effects on the displacement of care onto the general medical sector. Modifications in benefit plan design included the imposition of restrictions, exclusions, limitations, and penalties; provision of incentives; requirements for prior authorization; and retrospective denial of claims. This methodology is managing benefits.

Managing benefits changed into cost control through management of care, a methodology claimed to be more patient-focused. By limiting authorization of expenditures to only those services deemed medically necessary and appropriate, delivered in the least restrictive and least intrusive treatment settings, and only by previously designated qualified practitioners, advocates of managed mental health care believed that proper care could be delivered to patients at the appropriate times, in designated settings, by the right type of provider, in skillfully titrated amounts, and at considerable cost savings. Techniques used to achieve this end included management through contracting, profiling, credentialing, and educating hospitals; organizing hospitals into a specialized, accessible, and interactive network of behavioral health care providers; using mandated standardized pretreatment assessment and treatment planning methods; and requiring the use of standardized forms, restricted formularies, and outcomes management.

Though not yet achieved, the more progressive goals of managed behavioral health care are disease management, demand reduction, health promotion, and wellness. Health maintenance organizations (HMOs) and other capitation-based arrangements have fiscal incentives to use these strategies, but both efforts and results have yet to be really impressive. Nonetheless, the techniques used mean that managed care has and continues fundamentally to affect the role of the psychiatric hospital.

The federal government sought further cost containment. The Tax Equity and Fiscal Responsibility Act of 1982 (TEFRA) led to new methods to control Medicare costs, the most significant being diagnostic-related groups (DRGs) for reimbursement. With the end of cost-plus reimbursement and its replacement with reimbursement based on diagnosis, hospital profits for medical and surgical treatment began to decline. The behavioral health care industry was initially unaffected by DRGs, largely because psychiatric diagnoses were thought to lack sufficient power to predict the course of treatment. Thus, there appeared to be tremendous financial opportunities available in the relatively unregulated behavioral health care market. These opportunities were short-lived; the rise and fall of for-profit psychiatric hospitals were equally steep, as described earlier. With the application of DRGs to psychiatry, this fiscal advantage also dissipated. Thus, the federal government, through Medicare and Medicaid, fundamentally affects the role of the psychiatric hospital.

Although the modern era of managed behavioral health care began in the private sector, these principles and practices spread to the public sector. Medicaid Managed Care was initiated due to the spiraling costs of the Medicaid program. Between 1985 and 1993, Medicaid costs tripled, and the number of beneficiaries increased by more than 50%.

Other Governmental Considerations

Although state governments most directly affect the roles of psychiatric hospitals—through state laws, regulations, licensure, inspections, and investigations—the federal government has profoundly changed the roles of psychiatric hospitals through federal legislation and court decisions. Table 56.3–2 provides a summary of these influences over the last six decades.

The federal government's influence can be examined through the example of the right to treatment. Much of the right-to-treatment litigation has focused on establishing standards of care and concomitant staffing patterns. In the 1940s, the APA maintained there should be no less than 1 psychiatrist for every 150 hospitalized patients, 1 graduate nurse for every 40 patients, and 1 attendant for every 8 patients. No state hospital of the day met all of the APA's standards.

The right to treatment was initially articulated by Morton Birnbaum, a lawyer, and physician in 1960. There followed a series of lower-court cases: *Lake v. Cameron* (1966), *Rouse v. Cameron* (1966), *Nason v. Superintendent of Bridgewater State Hospital* (1968), *Wyatt v. Stickney* (1971), and *New York State Association for Retarded Children v. Rockefeller* (1973), the so-called Willowbrook case. Each of these is briefly explained in Table 56.3–2.

The U.S. Supreme Court decided three cases between 1975 and 1982 that might have established a right to treatment, meaning states that would be obligated to treat committed patients. In *O'Connor v. Donaldson* (1975), the Court found "A State cannot constitutionally confine, without more, a nondangerous individual who is capable of surviving safely in freedom by himself or with the help of willing and responsible family members or friends." In *Halderman v. Pennhurst State School & Hospital* (1977), the Court again did not reach the issue of a constitutional basis for a right to treatment or habilitation. In *Youngberg v. Romeo* (1982), the Court went the furthest it has to date when it held that persons with mental retardation who were involuntarily committed to institutions have "constitutionally protected liberty interests under the Due Process Clause of the Fourteenth Amendment to reasonably safe conditions of confinement, freedom from unreasonable bodily restraints, and such minimally adequate training as reasonably may be required by their interests.” Had the Supreme Court established a right to treatment, the roles of psychiatric hospitals might have been considerably expanded.

The major advances in the right to treatment in the 1980s occurred pursuant to the Civil Rights of Institutionalized Persons Act (CRIPA) of 1980. This act authorized the U.S. government to institute a civil action against any state whose officials, employees, or those acting on their behalf are “subjecting persons residing in or confined to an institution to egregious or flagrant conditions which deprive such persons of any rights, privileges, or immunities secured or protected by the Constitution or laws of the United States causing such persons to suffer grievous harm.” Under this authority, the Civil Rights Division of the U.S. Justice Department has been able to substantially bring the right to treatment closer to a reality for thousands of persons in a state, county, or municipal psychiatric hospitals by applying the standards of *Youngberg* to negotiate consent decrees. A consent decree is a document filed with the court in which the two parties sign a binding agreement in lieu of litigation.

Table 56.3–2.

Federal Government and Court Actions Defining the Role of Hospital Treatment Over the Last Six Decades

1955	The Mental Health Study Act of 1955 (Public Law 182) calls for a nationwide analysis and re-evaluation of the human and economic problems of mental illness. It leads to the formation of the Joint Commission on Mental Illness and Health.
1963	President John Kennedy submits to Congress a “Special Message on Mental Illness and Mental Retardation” that calls for a “wholly new national approach” to those two health problems.
1960	In *Dusky v. United States,* U.S. Supreme Court affirmed a criminal defendant’s constitutional right to have a competency evaluation before proceeding to trial and setting the standard for determination of such competence. This has subsequently meant many individuals are sent to state hospitals every year for competency evaluations.
1964	*Dixon v. Weinberger*, filed in U.S. District Court of the District of Columbia, claims that patients at St. Elizabeth’s Hospital have a statutory right to treatment and that those involuntarily committed under the 1964 Hospitalization of the Mentally Ill Act of the District of Columbia must be placed in the least restrictive setting consistent with suitable treatment.
1965	Medicare legislation is passed. It includes limited coverage for patients receiving active treatment in state hospitals in addition to those in general hospitals.
1966	The Social Security Amendments of 1965 (Public Law 89–97) adds Title XIX, Medicaid, to the Social Security Act. Medicaid funds psychiatric treatment in general hospitals for those under categorical assistance programs and who qualify as medical indigents, and it improves coverage for psychiatric illness under Medicare.
	In *Lake v. Cameron*, a U.S. court of appeals rules that an individual could not be committed to the hospital until

	hospital officials determined that there was no less-restrictive facility available to care for her.
	In *Rouse v. Cameron*, a U.S. court of appeals finds that a criminal defendant who is acquitted by reason of insanity and involuntarily committed to a psychiatric hospital has a right, legally enforceable through habeas corpus, to adequate and suitable treatment.
1970	*Wyatt v. Stickney* is filed in federal district court in Alabama, addressing the issue of detention without treatment of involuntarily civilly committed persons. The court subsequently finds that three fundamental conditions are necessary for adequate and effective treatment in public psychiatric hospitals: A humane psychological and physical environment, enough qualified staff to administer adequate treatment, and individualized treatment plans.
1972	In *Lessard v. Schmidt*, a federal district court decides that under the due process provisions of the Constitution, persons facing involuntary civil commitment are guaranteed the full array of procedural safeguards formerly guaranteed only to individuals charged with a crime.
1973	In *Souder v. Brennan*, a federal district court finds that patient–workers are covered by the Federal Fair Labor Standards Act, entitling them to minimum wages and overtime compensation.
1974	In *Donaldson v. O’Connor*, the U.S. Fifth Circuit Court of Appeals rules that a person who is involuntarily civilly committed to a psychiatric hospital has a constitutional right “to such treatment as will help him be cured or to improve his mental condition.” The U.S. Supreme Court issues its decision in this case on June 26, 1975, finding that “a State cannot constitutionally confine, without more, a nondangerous individual who is capable of surviving safely in freedom by himself or with the help of willing and responsible family members or friends.”

1975	The first class-action suit on the right to refuse treatment is filed for Boston State Hospital patients in a case originally known as *Rogers v. Okin* (right-to-refuse-treatment cases were basically decided on state-by-state basis to the end of the century, with very different rulings among the states).
1975	In *Drope v. Missouri*, the U.S. Supreme Court rules when deciding whether to evaluate a criminal defendant's competency, the court must consider any evidence suggestive of mental illness, even one factor alone in some circumstances. Therefore, the threshold for obtaining a competency evaluation is low. When the issue is raised, the motion should be granted. This means even more individuals sent to the state hospital for evaluation.
1976	In *Tarasoff v. Regents of the University of California*, the California Supreme Court rules that "when a therapist determines, or pursuant to the standards of his profession should determine, that his patient presents a serious danger of violence to another, he incurs an obligation to use reasonable care to protect the intended victim against such danger."
1978	In *Rennie v. Klein*, the U.S. Supreme Court rules that an involuntarily committed, legally competent patient who refuses medication has a right to professional medical review of the treating psychiatrist's decision. The Court left the decision-making process to medical professionals. This decision changed the long-standing practice whereby a committed patient could be treated over his object simply because he had been committed.
1979	In *Addington v. Texas,* the U.S. Supreme Court holds that the standard of proof in civil commitment hearings is "clear and convincing," a lower standard than "beyond a reasonable doubt."
1980	The Civil Rights of Institutionalized Persons Act allows the federal government to initiate actions against states whose public institutions, such as hospitals, prisons,

	nursing homes, and jails, deny residents their constitutional rights.
	In *Suzuki v. Yuen,* the U.S. Court of Appeals for the Ninth Circuit rules that involuntary civil commitment solely on the grounds of danger to property is unconstitutional.
1981	In a 5-to-4 decision, the U.S. Supreme Court rules that inpatients of public psychiatric institutions are not eligible for Supplemental Security Income (SSI) payments granted to mentally ill patients in other settings.
1982	In *Youngberg v. Romeo*, the U.S. Supreme Court decides that a person in an institution has a constitutionally guaranteed “right to personal security,” “a right to freedom from bodily restraint,” and the right to receive “such training as an appropriate professional would consider reasonable to ensure his safety and to facilitate his ability to function free from bodily restraints.”
	Congress enacts the Tax Equity and Fiscal Responsibility Act (Public Law 97–248), which sets the stage for a prospective payment system for Medicare.
1985	In *Ake v. Oklahoma,* the U.S. Supreme Court rules indigent criminal defendants have a right to a competency evaluation. The potential pool of persons who can be sent to state hospitals for evaluation expands again.
1990	The Americans with Disabilities Act (ADA) is enacted to eliminate discrimination against disabled persons. Title II says, “No qualified individual with a disability, shall, by reason of such disability, be excluded from participation in or be denied the benefits of the services, programs, or activities of a public entity, or be subjected to discrimination by any such entity.”
1991	The Patient Self-Determination Act, a part of the Omnibus Budget and Reconciliation Act of 1990, requires health care facilities that receive Medicare and Medicaid

	funding to provide information to adult patients about their right to make their own health care decisions, including the right to accept or refuse treatment and to execute advance directives about medical care.
1997	In *Kansas v. Hendricks*, the U.S. Supreme Court rules that sex offenders can be civilly committed because they “suffer from a volitional impairment rendering them dangerous beyond their control” and because “far from any premature objection, the confinement’s duration is instead linked to the stated purpose of the commitment, namely to hold the person until his mental abnormality no longer causes him to be a threat to others.”
1999	In *Olmstead v. L.C. and E.W.*, the U.S. Supreme Court rules that the ADA requires states to provide community placement for persons with mental disabilities if the state’s treatment professionals have determined it is appropriate, if it is not opposed by the individuals affected, and if it can be reasonably be provided considering state resources and the needs of other disabled persons.
	Publication of *Mental Health: A Report of the Surgeon General.*
2000	The Ticket to Work and Work Incentives Improvement Act permits states to increase the level of income disabled persons can earn before they become ineligible for Medicaid and extends the period that disabled persons can be employed and the income they can earn before losing Medicare coverage.
	Wyatt v. Sawyer (formerly *Wyatt v. Stickney*) settled.
	The Drug Addiction Treatment Act allows office-based heroin treatment by permitting qualified physicians to prescribe take-home doses of buprenorphine.
	Federal legislation authorizes $10 million over 4 years to establish up to 100 mental health courts.
	Federal rules are issued establishing a national uniform standard for protecting the privacy of medical records.

2001	The Surgeon General promulgates a national strategy for suicide prevention: *National Strategy for Suicide Prevention: Goals and Objectives.*
	The Health Care Financing Administration is restructured and renamed the Center for Medicare and Medicaid Services (CMS).
2002	The Department of Health and Human Services releases *Report to Congress on the Prevention and Treatment of Co-occurring Substance Abuse and Mental Disorders*.
2003	The President's New Freedom Commission on Mental Health puts out its report, *Achieving the Promise: Transforming Mental Health Care in America*.
2004	A federal district court in Oregon requires the state to eliminate a $250 copayment for hospital visits for the standard population of the Oregon Health Plan.
2005	The federal government, jointly through the Department of Health and Human Services (DHHS), the Department of Housing and Urban Development, the Department of Justice, the Labor Department, the Veterans Administration, and the Social Security Administration, put out *Transforming Mental Health Care in America. The Federal Action Agenda: First Steps*. This starts a multiyear venture to alter the forms and functions of the mental health system in the United States.
2006	The 2006 Budget Reconciliation Act alters Medicaid rules, such that states can impose premiums and higher cost sharing on beneficiaries, as well as allows states to provide scaled-back Medicaid benefit packages. One consequence is transferring some Medicaid beneficiaries to the rolls of the uninsured, with hospitalization going from Medicaid reimbursement to free care.
	The Substance Abuse and Mental Health Services Administration (SAMHSA) provides a training curriculum to reduce (or eliminate) the use of seclusion and

restraint: *Roadmap to Seclusion and Restraint Free Mental Health Services*.

The CMS publishes final rules on the use of seclusion and restraint in the *Federal Register*. The new limits (previously there were none) are: Adults, 4 hours; children and adolescents age 9–17 years, 2 hours; and children younger than age 9 years, 1 hour.

Implementation of Medicare Part D.

2007 The Agency for Healthcare Research and Quality (AHRQ) of the DHHS reports that there is no evidence base for the off-label use of atypical antipsychotics.

SAMHSA, in *An Action Plan for Behavioral Workforce Development*, reports "an anemic pipeline of new recruits to meet the complex behavioral health needs of the growing and increasingly diverse population in this country."

The AHRQ, in *Care of Adults with Mental Health and Substance Abuse*, reports that 6% of all community hospital stays were primarily for psychiatric or substance use disorders and nearly 25% included such a disorder.

Federal judges in Wisconsin question diagnoses invented to civilly commit sex offenders after expiration of their criminal sentence. In *Brown v. Watters* the diagnosis was "paraphilia not otherwise specified-nonconsent"; in *McGee v. Bartow* the diagnosis was "personality disorder not otherwise specified with antisocial feature." Neither is a *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (DSM-IV) diagnosis.

2008 The Paul Wellstone and Pete Domenici Mental Health Parity and Addiction Equity Act of 2008 (MHPAEA) amended the Public Health Service Act, the Employee Retirement Income Security Act (ERISA) and the Internal Revenue Code, to require group health plans and health insurance issuers to ensure that financial requirements (such as copays, deductibles) and

	treatment limitations (such as visit limits) applicable to mental health or substance use disorder benefits are no more restrictive than the predominant requirements or limitations applied to substantially all medical and surgical benefits.
2010	The Affordable Care Act was passed by Congress and then signed into law by President Obama on March 23, 2010. Titles I. Quality, Affordable Health Care for All Americans and II. The Role of Public Programs and V. Health Care Workforce have direct impact on psychiatric hospitals.
2012	U.S. Supreme Court rules in *National Federation of Independent Business v. Sebelius*on June 28, 2012, in a 5–4 ruling, that the Affordable Care Act is constitutional. The court defines the individual mandate as a tax and not a mandate and provides a choice for States to Opt-Out of Medicaid Expansion.
2013	A final regulation implementing MHPAEA is published in the Federal Register on November 13, 2013.
2013	Representative Tim Murphy (R-PA) introduces, on December 12, 2013, H.R.3717—Helping Families in Mental Health Crisis Act of 2013 which is the first comprehensive federal legislation addressing the needs of those with serious mental illness since President Kennedy’s Community Mental Health Act in 1963.
2014	Representative Ron Barber (D-AZ) introduces, on May 2, 2014, H.R. 4574—The Strengthening Mental Health in Our Communities Act, the House Democrats’ alternative to the bill filed by representative Murphy.
2014	U.S. Supreme Court Justice Ruth Bader Ginsburg files a dissenting opinion in *Burwell v. Hobby Lobby Stores, Inc.*, a decision that exempts employers from covering birth control (as required by the Affordable Care Act) if the employer objects on religious grounds. One of Ginsburg’s queries was, could Scientologist employers not cover antidepressants on religious grounds?

2014	On April 1, 2014, President Obama signed into law the Protecting Access to Medicare Act (H.R. 4302), which includes a demonstration program based on the Excellence in Mental Health Act. This act (1) creates criteria for "Certified Community Behavioral Health Clinics," (2) provides $25 million that will be available to states as planning grants to develop applications to participate in the 2-year pilot, (3) stipulates that 8 states will be selected to participate in the 2-year pilot program, and (4) requires participating states to develop a Prospective Payment System for reimbursing Certified Behavioral Health Clinics for required services they provide.

On July 26, 1990, the Americans with Disabilities Act (ADA) passed and established a "clear and comprehensive prohibition of discrimination on the basis of disability." Title II is of greatest interest because this title covers state and local government services, and so includes public hospitals. Title II indicates "no qualified individual with a disability shall, by reason of such disability, be excluded from participation in or be denied the benefits of the services, programs, or activities of a public entity, or be subject to discrimination by any such entity." One regulation promulgated to operationalize this Act states, "A public entity shall administer services, programs, and activities in the most integrated setting appropriate to the needs of qualified individuals with disabilities." This marks a shift from the long-standing standard, "least restrictive alternative," to the new standard, "most integrated setting." The ADA was seen not so much as a way to improve services within hospitals as a way to force states to move patients out of these institutions.

The hallmark Supreme Court decision to date applying the ADA to persons in hospitals is *Olmstead v. L.C.* (1999). The case involved two women who were in a Georgia state hospital despite the fact that treatment professionals had concluded each could be appropriately treated in community-based programs. The Court found that the "unjustified isolation . . . [of persons with mental disabilities] is properly regarded as discrimination based on disability." The basis for this finding was that "Institutional placement of persons who can handle and benefit from community settings perpetuates unwarranted assumptions that persons so isolated are incapable or unworthy of participating in community life.” The justices then made a leap to the conclusion that institutional confinement “severely diminishes the everyday life activities of individuals, including family relations, social contacts, work options, economic independence, educational advancement, and cultural enrichment.” Thus, began the most recent wave of translocating persons from a public psychiatric hospital to alternative settings. Apparently, general hospitals and private hospitals were deemed “in the community.” So too, based on the most recent data, are jails and prisons.

FULFILLING THE ROLE

The hospital fulfills its role in the care and treatment of psychiatric patients in a prescribed way. Efficacious treatment derives from effectively performing each step.

Assessment

Assessments are done by individual practitioners of different disciplines. An admission assessment is conducted by a physician, preferably a psychiatrist. This assessment, done at the patient’s presentation to the hospital, documents the chief complaint; the basis for admission and history of the present illness; relevant past psychiatric history, family history, and social history; a complete mental status examination; a substance abuse screen; and a risk assessment (suicide, homicide, fire setting, others). This assessment should lead either to admission or to nonadmission with an outpatient plan.

A nursing assessment is completed as soon after the patient’s arrival on the ward as possible, but no later than 8 hours. The nursing assessment overlaps in part with the physician admission assessment but covers some areas in less detail and others in more detail. The nursing assessment includes a pain assessment, a falls risk assessment, skin care concerns, and special nursing care needs.

The third assessment that needs to be completed proximate with admission is the medical history and physical examination. This is done either by the admitting psychiatrist or by an internist, depending on the staffing of the hospital. Besides attending to general medical history, particular attention needs to be paid to how medical disorders and physical findings might be affecting the psychiatric presentation.

All three of these assessments need to cover the areas of alcohol and substance use/abuse. Positive screens lead to an alcohol and drug abuse assessment, preferably completed by staff with expertise in this area.

Other disciplines need to complete their assessments prior to the interdisciplinary team (IDT) meeting at which the Treatment and Recovery Plan (TRP) is developed. These assessments include those by social work—the psychosocial assessment—and by rehabilitation services (often inappropriately referred to as "activities therapy"). The psychosocial assessment needs to provide information from collateral sources when such information is necessary to complete the database, there are collateral sources to contact, and the patient has provided permission (release of information) to contact specific individuals. Some hospitals include a psychology assessment on all admission; others use psychologists who function as consultants, and psychological assessments are conducted only on referral. Dietician assessments are often done routinely; medical specialty assessments are done on referral.

Formulation

Traditionally, the weakest part of the process is from assessment to intervention, and one is often left out entirely. The formulation needs to be seen as a fundamental part of the process. The formulation pulls the data together into a coherent picture of the individual. It is not a brief restatement of the facts of the case. The formulation takes the symptoms, which are the basis for an understanding of the *patient*, and adds significant historical information to provide an understanding of the *person*.

Leaving out or improperly constructing the formulation leads to the loss of important information that does not directly translate into diagnoses but is crucial for effective treatment planning. Formulations may be recorded as components of each assessment—for example, psychiatric formulation, nursing formulation—and then brought together at the IDT meeting, or they may be written at the IDT meeting by the psychiatrist drawing from all of the assessments.

Treatment Planning

Because treatment must commence at the onset of hospitalization, the Initial Treatment and Recovery Plan (ITRP) is, of necessity, a multidisciplinary process. The ITRP is initiated by the admitting psychiatrist and nurse based on their assessments. Other disciplines add to the ITP as they conclude their assessments.

Whereas the ITRP provides the basis for directing treatment during the first few days of hospitalization, the rationales for specific interventions must be included in either the assessments or in the progress notes. For example, each medication ordered by the admitting physician must have a documented rationale. It is not sufficient simply to state that medications taken prior to admission are being continued because this does not provide any basis for the medications. Stating that aripiprazole and clozapine, for instance, are being prescribed fails to justify polypharmacy without providing a basis beyond recording that these were the medications prescribed by the CMHC psychiatrist. Furthermore, any as-needed (PRN) medication ordered at admission needs to have a rationale, one that is specific to the patient. Ordering lorazepam 2 mg orally for agitation and haloperidol 5 mg orally for severe agitation is not sufficient. Such orders are neither specific to the patient nor do they inform the nurse what the prescriber means by “agitation” and what he means by “severe agitation.”

The TRP expands upon the ITRP and derives from an *interdisciplinary* process. The IDT is composed of professional and paraprofessional staff, as well as the patient. The patient, assisted by staff, is free to invite any other individuals to this meeting, for example, family members, friends, or advocates. The purpose of the IDT meeting is to *write* the TRP. It is not a time to sanction a TRP written before the meeting by one member of the IDT. The meeting uses multidisciplinary assessments as the basis to create an interdisciplinary treatment plan.

The creation of the TRP follows an orderly process. The IDT establishes, with the patient as the lead, the problems, which in the inpatient setting are predominantly barriers to discharge. Other problems may be addressed, depending on the expected length of stay of the patient. For each problem, there is a long-term goal (LTG) and a set of short-term goals (STGs) or objectives. The goals are the patient’s goals, not the staff’s goals for the patient. Hence, problems and goals belong to the patient. For each STG, there is a series of interventions. Interventions are what the staff does, not what the patient does. Each intervention under an STG must specifically assist the patient to move toward the achievement of that STG.

STGs need to be specific, measurable, attainable, realistic, and timely (often referred to by the acronym SMART). STGs are intermediate steps toward the accomplishment of the LTG. Small steps that the patient reaches at intervals reinforce the patient and the staff.

Interventions need to specify the frequency of the intervention, the duration of the intervention, and the name of the intervener. For example, “Nurse Nightingale provides Medication Education Group, Tuesday and Thursday, 10:00–10:45 a.m.”

Common errors in interventions include the following:

1. Writing job descriptions: “Nurse Nightingale will administer medication and monitor for side effects.”
2. Failing to document intervener and/or duration: “Anger Management Group Wednesdays.”
3. Including interventions unrelated to the STG, such as “Dr. Woodward will meet with patient Mondays, 1:00–1:20 p.m. to review concerns about weight gain from clozapine,” when the STG is “Patient will have one five-minute telephone conversation per day with mother for three consecutive days without telling her mother to drop dead or piss off.”
4. Using terms that communicate no specific intervention (and can often be dangerous to staff if done wrong) such as “encourage patient to . . . ” or “assist patient to . . . ” If such interventions are used, the intervention must be explicit about how the “encourage” is to be done.

The ideal sets of interventions are clear, concise, and explicit. If the entire IDT were out sick one day, covering staff should be able to treat the patient by performing the interventions.

The TRP is the road map for the patient’s treatment. Active treatment—a concept or phrase used by many certifying entities—is defined as that treatment found as an intervention on the TRP that moves the patient toward the achievement of an STG that moves the patient toward the achievement of an LTG that addresses one of the patient’s problems. A simple rule when one is calculating active treatment hours for a patient is, “if it’s not on the treatment plan, it’s not active treatment.”

Progress is recorded in progress notes. These are written pointedly addressing STGs. Each note needs to be labeled with the discipline of the intervener and the STG being addressed. Thus, there would be no nursing staff note reading “Patient ate well and slept well” unless eating and sleeping were problems on the TRP with specific LTGs and STGs.

The initial TRP is completed within a specified time frame, varying between 1 and 10 days, and specified by the facility's policies and procedures. The TRP is reviewed through IDT meetings at which treatment plan reviews (TRPRs) are conducted. The TRPR builds on the TRP, uses progress or lack thereof noted in the progress notes, and modifies the TRP as needed. TRPRs also occur on a schedule. In units with short lengths of stay, the TRPR occurs from daily to every 3 days. In intermediate length of stay units, TRPRs occur weekly for 60 days, then every 2 weeks for 60 days, then monthly. In longer stay units, TRPRs may occur monthly after the TRP done at 10 days.

Besides occurring on a scheduled basis, TRPRs need to occur in response to a patient's clinical need. Many hospitals have thresholds that, when met, require a TRPR to be held within one business day. Such thresholds included (1) any episode of seclusion or restraints; (2) a specific number of episodes of seclusion or restraint or a specific number of hours of seclusion or restraint within a designated time frame; (3) the administration of any psychiatric medication PRN or a given number of PRNs within a specified time frame; (4) the initiation of 1:1 observation; and/or (5) any serious incident, for example, patient-on-patient assault, patient-on-staff assault, or suicide attempt.

The TRP needs to be comprehensive or account for why it is not (either in the TRP or in the hospital's policies and procedures) in all but acute care settings. Thus, the TRP would be expected to address all of the patient's psychiatric and medical problems on longer-term units. A TRP could provide interventions for those problems that are impediments to discharge and address other problems as resources allow; this is often the case on intermediate-length-of-stay units. A CTP could address only those problems that are impediments to discharge with the expectation other problems will be addressed in treatment after discharge; such an approach is often employed on short-term units. This does not mean that maintenance treatments will not be provided for acute or chronic problems that are not the focus of the hospitalization, such as antihypertensive medications, treatments for gastroesophageal reflux disease or constipation, and hypnotic medications.

There is a new emphasis on tying the hospital TRP to a community TRP for persons with SMI in systems of care (traditionally CMHCs, but now also health homes and other integrated care settings). In the person-centered approach, the community TRP starts with the individual's "life goals.” Community clinicians, support and outreach staff (peer and nonpeer workers), and naturalistic resources are channeled toward assisting the individual to move ever closer to his life goals. Hospitalization is usually a detour on the journey toward one’s life goal, so focusing on problems that are impediments to discharge is in the service of returning the person to the community to take up the pursuit of his individualized life goals. To do so effectively, the hospital TRP should record the life goals as anchor points.

Treatment

Treatment planning is necessary but not sufficient for effective treatment to ensue. Members of the IDT plus other staff need to provide integrated treatment that follows the plan.

Psychopharmacologic treatment is a mainstay of contemporary inpatient treatment but must be prescribed (physician), dispensed (pharmacist), and administered (nurse) with awareness of contemporaneous interventions. Either initiating psychotropic medication or adjusting medication regimens is considered the sine qua non of inpatient psychiatry. Of course, not all admissions require medication, and distinguishing these patients from all others is an important function of the assessments and observations that are unique to the inpatient setting.

In prescribing medication, the attending psychiatrist must communicate the reasons for the medication and its side effects not only to the patient (obtaining informed consent before ordering the medication) but also to all members of the IDT. Hence, the importance of monitoring progress and informative progress notes accompanying each order.

PRN medications warrant particular attention. PRN medication transfers de facto prescription authority from physician to nurse because the nurse decides when and how much medication the patient will receive (within the parameters set by the physician). Unless the physician checks daily on the total dose of each PRN medication given, it is not possible for the physician to relate the patient’s progress to the medication administered. Hospitals have taken various approaches to PRN psychotropic medication, including eliminating them entirely, limiting the orders to short-term orders, for example, 3 or 5 days, or allowing PRNs only on admission units and not on other units within the hospital.

Well-written progress notes by the psychiatrist assist the nurse in writing useful nursing progress notes. Writing “patient remained calm and cooperative throughout shift” may convey no useful information if, for example, the patient is depressed with a recent suicide attempt and is externally calm and cooperates because it takes less energy and concentration to do so than not to do so. A physician progress note detailing the specific target signs and symptoms for which antidepressant X has been prescribed provides the foundation for the nurse to write progress notes that focus on those signs and symptoms. If the physician simply writes antidepressant X for “dysphoria” or “depression,” progress notes by other staff members are likely to be equally uninformative.

Another function shared predominantly by the psychiatrist, and the nursing staff (Registered Nurse [RN], Licensed Practical Nurse [LPN], Mental Health Technicians [MHTs]) is patient safety. Maintaining a safe milieu and maximizing the safety of each patient and staff depends on (1) active, individualized treatment, (2) levels of observation and privileges geared to the patient’s level of risk, (3) prompt and skillful response to patient aggression, (4) modification of therapeutic interventions as the nature and/or level of risk changes, and (5) continuing staff education and training.

Level of observation and privileges serve the function of patient safety and should not be used as rewards for compliance with process variables like attendance at groups. When the level of observation is for the risk of harm to self, the most noteworthy harm being suicidality, the hospital needs a process by which increasing the level of observation, that is, more staff oversight can easily be instituted by a physician or RN, but decreasing the level of risk can only occur on a written physician’s order after a face-to-face evaluation. In some hospitals, this can only be done by the attending psychiatrist. Telephone orders and verbal orders should never be accepted for lowering the observation level.

In addition to medication, inpatient treatment involves individual sessions and group interventions. Individual psychotherapy is the exception these days, although this modality continues to be used in some public and some private hospitals. There are a few hospitals in which intensive psychotherapy is the mainstay of inpatient treatment. The programming of individual sessions with the social worker to focus on discharge planning is the rule. Individual sessions with nursing staff to practice skills taught in groups should occur at least through the day and evening shifts (and the night shift if appropriate to the patient’s needs).

Group interventions fall under the heading of psychosocial rehabilitation. In general hospitals, these groups occur on the unit. In state hospitals and in some private hospitals, these interventions are delivered off-ward in areas of the hospital, often referred to as the “treatment mall.” There are several advantages to setting up groups or classes in a centralized location, including the following:

1. Patients follow a variant of the “work order day”; patients, like staff, “commute” to where they spend their daytime hours; in the case of patients, they live in one place (the unit) and get their treatment in another location (the mall); lunch is often provided at the mall.
2. Pooling patients and consequently pooling staff means that a large number of different groups can be provided per hour, rather than having the same group occur simultaneously in multiple locations.
3. The issue of patients remaining in bed, watching TV, or participating in other diversions is handled by institutional policy and practice rather than day by day, case by case.
4. The safety of staff and patients is increased because there is more staff available for an emergency.
5. Professional and paraprofessional staff spend more time with patients because patients and staff are at the treatment mall during mall hours.

Newly constructed hospitals (see Table 56.3–1) are designed with accessible treatment mall locations. The use of perimeter security with significant freedom of travel for patients within the building eases access to mall-based treatment and maximizes patients’ autonomy (see Fig. 56.3–5). One controversy surrounding the use of treatment malls at hospitals is whether or not the hospital can require all patients to attend the mall. Does the right to refuse treatment also mean the right to not go where treatment is provided? In one model, patients have a right to refuse treatment, but patients do not have a right to determine where they are at the hospital at any given time. If this were a right, patients could refuse to remain behind any locked door. Patients must go to the treatment mall, but the hospital must provide a place for them on the mall if they refuse to attend the groups they are scheduled to attend. A corollary controversy in this model relates to the issue of whether staff can lay hands on a patient if the patient refuses to go to the mall. Staff can lay hands on a patient if there is an emergency, and leaving a patient on a ward with no staff because of the patient’s refusal to leave the ward would constitute an emergency. In another model, where patients cannot be compelled to leave the unit for groups, hospitals have created units with and without an off-unit requirement. There are benefits and drawbacks of each type of unit and absent safety concerns; a patient makes his choice based on his valuation of the different benefits of each type of unit.

Although there are no controlled studies of the operation and effectiveness of treatment malls, data collected at individual hospitals seem to support (1) rapid adjustment of patients to a change to the treatment mall approach; (2) very low use of hands-on procedures to move patients; (3) decreased rates of seclusion and of restraint without accompanying increases in the total daily dose of antipsychotic and/or antimanic medications or of benzodiazepines; and (4) improvement in patients' sleep with fewer doses of hypnotics. Most importantly, patients do seem to learn skills through the use of mall-based groups.

Clinicians doing hospital-based treatment, just like their colleagues doing outpatient treatment, need to be mindful of three contemporary concepts: recovery, evidence-based treatment, and trauma-informed care. Practitioners of all clinical disciplines have struggled to achieve consensus definitions of these percepts. SAMHSA's definitions are as follows:

Recovery: A process of change through which individuals improve their health and wellness, live a self-directed life, and strive to reach their full potential.

Evidence-based: Demonstrating effectiveness in empirical research that meets a standard of scientific rigor as embodied in minimum review requirements, which include the stipulation that an intervention must have demonstrated one or more positive behavioral outcomes ($P \leq .05$) in substance abuse and/or mental health in at least one study using an experimental or quasi-experimental design.

Trauma-informed care: It is a strengths-based service delivery approach that is grounded in an understanding of and responsiveness to the impact of trauma, that emphasizes physical, psychological, and emotional safety for both providers and survivors, and that creates opportunities for survivors to rebuild a sense of control and empowerment.

A well-functioning psychiatric hospital would incorporate these principles into its therapeutic offerings by having expertise in and providing, among other offerings: cognitive behavior therapy for psychosis (CBTp) cognitive enhancement and restructuring therapy (CERT); cognitive restructuring for PTSD; cognitive therapy for psychosis (CT-R); dual recovery (mental illness and substance abuse); dialectical behavior therapy; family support and treatment; fire-setting treatment; grief therapy; illness management and recovery (IMR); individualized exercise plan (IExP); leisure skills development; medical care and treatment; mental illness and problematic sexual behavior treatment (MIPSB treatment); motivational interviewing and motivational enhanced therapy; person-centered approach; pharmacotherapy; positive behavioral support plan; readiness for change interventions (individual and group); sensory modulation; vocational rehabilitation; and wellness management recovery action plan (WRAP). Behavioral interventions, generally under the direction of a psychologist with particular expertise in this area, need to be available at all hospitals. This is of paramount importance in hospitals that have units with intermediate- or long-stay patients. The behavioral plan is based on a functional assessment of the target behavior to be modified or eliminated. The plan provides a series of responses aimed at reinforcing some behaviors and extinguishing others. All direct care staff must be trained in the specific interventions to be used for a specific patient. Preferably, the hospital has a way to document such training and to ensure that any staff assigned to work with a patient who has a behavior plan is trained in that plan.

During hospital treatment, a major controversy has been patients' "right to smoke." It is unclear how this is a right. If it were, patients would also have a "right to drink." No one argues the latter, so why the former? Forbidding smoking on the unit has generally occurred at all hospitals. Moving that restriction to a designated area within the hospital was the next step. Patients can often be seen at the perimeters or in the courtyards of the hospital smoking. Many hospitals have progressed to prohibiting smoking anywhere in the building, and some even prohibit smoking on the hospital grounds. Hospitals should neither be in the business of selling cigarettes nor use staff to purchase cigarettes for patients—a practice referred to as "making a cigarette run." Given that there is now a range of aids to stopping smoking—gum, patches, pills, support groups—these should be made available to patients and to staff. Nicotine replacements should be used as a transition to becoming nicotine-free; too often, they become permanent fixtures on the patient's pharmacologic plan. It was not that long ago that state hospitals received free tobacco from cigarette companies, purchased cigarette papers, and paid staff, and/or had patient groups whose focus was to roll cigarettes. The rolling machines had been purchased with state funds. Progress in smoking cessation needs to continue, particularly given the increased morbidity and mortality of persons with chronic mental illness. The role of the hospital should be to teach patients and support their efforts to maximize a healthy lifestyle. Wellness programs are being conducted at many hospitals and are well worth supporting.

Discharge Planning

The aphorism “Discharge planning begins at the time of admission” is, of necessity, particularly true today, given all of the pressures surrounding the length of stay. Although the discharge process is primarily the responsibility of the IDT’s social workers, it is a mistake to assume it is their task alone. Discharge planning is an interdisciplinary process.

Discharge planning is processed by the social worker interacting with the patient and IDT members until the TRP. At this point, the discharge plan becomes an integral part of the TRP. Whether discharge-related issues are identified as one of the problems on the TRP depends on the patient’s specific circumstances. Discharge might be a problem if the patient is homeless, cannot return to the residence from which they were admitted, or is an illegal immigrant with no eligibility for entitlements. An often-missed problem related to effective discharge is recidivism; that is, the patient has multiple admissions, generally with short community tenure between them. Recidivism is often too quickly ascribed to noncompliance with medication without the IDT doing a thorough investigation of the etiology of repeated admissions. Noncompliance may well be a factor in any short time period between admissions, but this may also be accounted for by a number of other factors. Often ignored is the contribution to stabilization made by the structured environment of the hospital. This is often the primary factor in recommending discharge to step down over “home” to allow for transition with continued structure. Often commented on but inadequately addressed is the use of alcohol, marijuana, other street drugs, and other prescribed medication even in a medication-compliant patient. There is also the contributing factor of secondary gain—the hospital may be the locus of the best quality of life the patient has experienced for years or even decades.

Discharge planning involves the establishment not only of sites of service and appointment times but also of efficacious linkage strategies. The steps that need to be taken to maximize the likelihood that the patient will actually make it to their first appointment with the outpatient psychiatrist are of paramount importance. Linkage also involves providing to the outpatient psychiatrist, outpatient therapist, and other appropriate personnel pertinent information in writing. A copy of the instructions given to the patient should reach the outpatient sites *before* the patient arrives for their first appointment; the discharge summary needs to follow shortly thereafter. So too does the TRP, so that the community can incorporate the work the hospital has done into the community TRP, just as the hospital incorporated the work the community had done into the hospital TRP. Phone contact from inpatient psychiatrist to outpatient psychiatry is advisable for any case seen as needing more than the usual written communications.

SPECIAL POPULATIONS

This section has focused on the role of the hospital in serving the general adult psychiatric population. The hospital serves many other populations, defined either by their demographics or by specific service needs.

Children and Adolescents

Twenty-one percent of U.S. children aged 9 to 17 years have a diagnosable mental or addictive disorder causing at least minimal impairment, and 5% to 9% of children this age have a serious emotional disturbance that causes extreme functional impairment. Significant numbers of children and adolescents in need of treatment do not receive behavioral health services. When children's mental health services are unavailable, unaffordable, or inappropriate, many young people end up in the child protection or juvenile justice systems.

Children and adolescents represent approximately 7% of the total mental health inpatient population. However, children's services receive a disproportionally low fraction of what adults receive for inpatient services, despite the fact, that on average, children's inpatient treatment is about 1.5 times as expensive as adult inpatient treatment.

Although the number of available inpatient psychiatric beds decreased, the admission rates of children and adolescents to psychiatric hospitals increased over the last few decades. Between 1986 and 1997, the number of youth admitted to inpatient services increased by 143%, and the rate per 100,000 youths increased by 119%. As the number of inpatient beds and specialized staff to care for children and adolescents with serious emotional disturbance has decreased, the number of families relying on hospital EDs for psychiatric services has increased. ED physicians report seeing a large number of children whose parents have simply run out of options for care.

Inadequate hospital-based and other services have created cohorts of labeled children. “Boarder kids” are children stuck for days, weeks, or even months in pediatric wards because there are no beds in a psychiatric hospital or ward. “Wait-list kids” wait months for case management or outpatient services. “Stuck kids” are in psychiatric hospitals but cannot leave because there is no place for them to go.

There are many factors that complicate the role of the hospital in the care and treatment of children and adolescents. Alcohol and illicit drugs are major problems. Current alcohol use is 36.2% for 17-year olds, 19.9% for 15-year olds, and 6.5% for 13-year olds. Among youth ages 12 to 17 years, about 12% are current illicit drug users. Annual suicide attempts in 15- to 24-year olds have surpassed 1 million in the United States, and suicide is the third-leading cause of death for this age group. Age-specific mortality rates from suicide are 1.6 per 100,000 for 10- to 14-year olds, 9.5 per 100,000 for 15- to 19-year olds, and 13.6 per 100,000 for 20- to 24-year olds. Almost half of the students with mental disorders drop out of grades 9 through 12, and of those dropouts, 73% are arrested within 5 years of leaving school. Children and adolescents with serious emotional disturbance often live in families with multiple risk factors and vulnerabilities, including single-parent households, poverty, and family history of substance abuse, violence, mental disorders, and/or felony convictions.

Although the challenges for families of children and adolescents with emotional and behavioral problems are great, best practices emphasize collaboration with families when coordinating care for the child. Inpatient facilities have placed an increasing emphasis on incorporating the family and other relevant support systems into a child’s treatment plan.

Today, children and adolescents are likely to receive mental health services in what is referred to as “systems of care.” Systems of care provide a spectrum of mental health and other necessary services organized into a coordinated network from community-based and least restrictive treatment settings and case management to intensive inpatient psychiatric care. Systems of care rely on “wraparound services.” The values underlying systems of care include a focus on the individual child and family, the provision of services within the most normalized environment that meets the youth’s need, the creation of partnerships with families, the use of a strength-based orientation, the creation of an environment of cultural competence, the provision of unconditional care, and the use of 24-hour institutional care at various points in time. Systems of care do not eliminate the need for inpatient level of care but often shorten lengths of stay.

As the wraparound model appears to have evolved into a best practice in the care of the most difficult children and adolescents, it is important to note that inpatient hospitalization treatment is not a failure of the wraparound model but one of its service components. Thus, the hospital plays a key role in wraparound services.

A challenge that most states face is providing services to children with emotional and behavioral disturbances when they age out of the child system. The eligibility requirements for services in a state’s adult system are many times narrower than the eligibility in the child system, so some transition-age youth who have been receiving services for years are screened out, leaving them without care and treatment. A vulnerable time for a young adult is exacerbated by the states’ need to restrict its eligibility pool for publicly funded mental health services.

Veterans

The veterans’ hospital system was established after World War I when veterans were entitled to health care benefits and compensation. States were unable to handle the needs of this population, given that there were hundreds of thousands of U.S. soldiers “wounded not mortally” and uncounted numbers who suffered from neuropsychiatric conditions.

On his last day in office in 1921, President Woodrow Wilson signed into law a bill supporting $18.6 million for the establishment of hospitals for veterans. The years 1921 to 1923 saw the provision of more than 6,000 beds in new veteran’s hospitals across the United States. From 1923 to 1945, there was a considerable expansion of hospital beds. Following World War II, the VA was entirely reorganized. In the decades following World War II, VA hospitals accounted for only a small percentage of the hospitalized population. Trends in bed use shifted, however, such that between 1955 and 1975, the number of VA inpatient episodes increased by 143%, whereas state and county mental hospitals decreased by 37%.

In the mid-1990s, the VA shifted its traditional focus on inpatient care and dramatically expanded its outpatient services. Between 1995 and 2001, the number of occupied annual inpatient psychiatry beds fell by 58% in VA hospitals, the length of stay decreased by 52%, and the number of veterans treated in the VA outpatient system increased by 27%. This shift, and the reorganization of the Veterans Health Administration (VHA) into 22 smaller, semiautonomous networks, may be contributing to the VA's apparent inability to meet the needs of veterans from combat in Afghanistan and Iraq. And that need is substantial. A nationally representative sample drawn from the National Health and Resilience in Veterans Study showed that the current and lifetime prevalence of PTSD in veterans was 4.8% and 8%, respectively. PTSD came from combat and noncombat situations and was associated with elevated risks of severe psychiatric disorders and suicide.

Efforts were initiated in 2006 to substantially improve the capacity of VA hospitals to meet the increasing psychiatric need of veterans. The VHA struggled to provide the necessary service. A 2010 report estimated that 18 veterans a day die by suicide and 950 suicide attempts occur each month among veterans receiving services through the VAH. Between 2010 and 1014, VA hospitals were the subject of scandals and problems, with systemic problems including turning away veterans who needed services and who then suicide, maintain secret waiting lists to create the appearance that delay in service was much shorter than it was, putting out false performance reports, covering up suicide attempts and running facilities in which illicit drug dealing was routine practice. As one commentator said, “the VAH is a bright, shining example of misguided priorities and terrible mismanagement.”

Veterans seek and/or receive treatment out of VHA settings for a number of reasons: The veteran is not service-connected for a psychiatric disability, the veteran prefers treatment out of the VHA, the veteran is a committed pursuant to a forensic status, or in some jurisdictions, the veteran refuses voluntary admission and requires civil commitment. Thus, continuity of care can be particularly problematic as the veteran moves in and out of the VA, public, and private systems of care.

The challenges facing the VAH are significant. In 2014, there were 24 million veterans in the United States, about one-third of whom were enrolled in VA care. There are 21,000 mental health professionals to meet this need, but only 3,000 are psychiatrists. The expectation is that the Veterans Access, Choice, and Accountability Act of 2014 will improve the ratio of VA psychiatrists, non-VA psychiatrists, and other mental health clinicians available to treat veterans with psychiatric disorders. The VA MISSION Act authorizes or expands several programs with the intention of recruiting and retaining health care providers in the Veteran's Health Administration. Among other things, the Act increases the maximum amount of student loan debt that may be reduced under VA's Education Debt Reduction Program (EDRP); authorizes designated scholarships for physicians and dentists under the VA Health Professional Scholarship Program (HPSP); establishes the VA specialty education loan repayment program to incentivize VHA employees to pursue education and training in medical specialties for which VA determines there is a shortage; establishes a pilot Veterans Healing Veterans Medical Access and Scholarship Program, and extends eligibility for VA's EDRP to clinical staff working at Vet Centers. The Veterans Access, Choice, and Accountability Act of 2014 (VACAA) required an increase in the number of GME positions by up to 1,500 over a 10-year period, beginning July 1, 2015, through 2024, with an emphasis on primary care, mental health, and other specialties the VA Secretary deems appropriate. The VACAA also required that the expansion focus on creating new programs at VA facilities where there had not previously been GME training and that the new positions be awarded for training in rural or otherwise underserved areas. As of September 2017, the VA had allocated about one-third of these new positions; it has not completed the expansion. Instead, the VA's objective is to complete the expansion by 2025.

Individuals active in the military receive their psychiatric inpatient treatment in Department of Defense hospitals. Of major concern for this population is suicide. The U.S. Army suicide rate exceeds the civilian suicide rate with substantially elevated suicide rates following psychiatric hospitalization—an eightfold increase for 3 months following a psychiatric hospital discharge and a fivefold increase for 12 months after psychiatric hospitalization. The Patient-Centered Community Care (PCCC) program contracts were awarded in September 2013 to provide inpatient and outpatient specialty care and mental health care for eligible veterans when the local VAMC cannot readily provide the services, such as when there is a lack of available specialists, there are long wait times, or there is an extraordinary distance from a veteran’s home.

Substance Abuse Comorbidities

Persons whose alcohol and/or substance use require hospital-based treatment fall into two categories: Those with so-called “straight substance abuse,” meaning that there is no other mental illness that is the focus of treatment, and persons who are dually diagnosed with a mental illness and a substance use disorder both of which require active treatment.

Treatment for substance use in either population requires detoxification when such is necessary and then treatment initiating prevention of relapse and recovery. Relapse and recovery are lifelong enterprises that may or may not involve inpatient treatment. With the exception of detoxification of persons at high medical risk, all the services for persons with substance abuse or individuals dually diagnosed can be found at a hospital and nonhospital loci of care.

Perhaps the major shift in the treatment of persons with dual disorders that occurred in the latter part of the 20th century was the movement from consecutive treatment to concurrent treatment. For decades, there was the belief that one could not address other psychiatric disorders until one had first addressed alcohol and/or substance abuse or dependence. Currently, efficacious treatment is considered to be treatment that addresses both at the same time.

Because the rate of alcohol and substance abuse is quite high in persons with other *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5) disorders, hospitals need to have expertise in substance abuse assessments and treatment at all levels of service. Many a diagnosis will be missed if the attending psychiatrist or the C-L psychiatrist is not thinking about the potential roles that alcohol and illicit drugs may be playing in the patient’s presentation. The legalization of marijuana or medical marijuana in some states is presenting new dilemmas for psychiatric hospitals and C-L psychiatrists. It is too soon to tell how this will be dealt with in different states, and within one state, in psychiatric inpatients settings in different types of hospitals.

Geriatrics

Patients older than the age of 65 years and those deemed “functionally geriatric” are treated in units with mixed-aged populations in some hospitals and on psychogeriatric units in others. The involuntary admission of older adult individuals varies greatly from state to state, in that some state statutes prohibit the involuntary admission of persons with any form of “organic brain syndrome” as the basis for the commitment, whereas others do not.

Older adult patients have special needs that the hospital must attend to (1) greater comorbidity with medical disorders; (2) increased likelihood of delirium; (3) possibility of their having another disorder that is confused with dementia, especially major depressive disorder; (4) greater need that all other medications they are taking be considered when the assessment is done and when psychopharmacologic recommendations are made; (5) higher suspicion for impaired capacity to consent to treatment; and (6) more likely to need additional social work care and services to assist for example in Adult Protective Services (APS) reports, identifying and contacting alternative decision markers, addressing end of life care concerns.

Of particular concern is the use of antipsychotic medication in older adult patients. In 2005, the FDA warned that second-generation antipsychotic medication was associated with an increased risk of death in older patients with Alzheimer’s disease and other age-related dementias. In 2008, the warning was expanded to include first-generation antipsychotics. Subsequently, a Harvard Medical School study of older adults, new users of antipsychotic medication showed that haloperidol had twice the mortality rate of the atypical antipsychotics, and among the atypicals, quetiapine had the lowest mortality rate. Another class of medications of concern is benzodiazepines, ubiquitous in their use in hospital settings to quiet agitated patients, including older adults. A case-controlled study using Quebec, Canada health insurance data showed chronic use of benzodiazepines by older adult patients was associated with about a 50% increase in Alzheimer disease 5 to 10 years after a period of 90 or more days of use, with benzodiazepines with half-lives of greater than 20 hours carrying the greatest risk. Thus, caution should be used in the inpatient management of older adult patients by using benzodiazepines for longer than brief—up to 90 days—treatment.

Staff in any of the hospital services should consider the need for, and implement if necessary, a complete organic medical workup, formal cognitive assessments, and referral for follow-up services that are age-sensitive.

Developmental Disabilities Comorbidities

Most states have deinstitutionalized persons with developmental disabilities/delays at an even greater pace than their population with chronic mental illnesses. That means that former residents of developmental disability facilities who would not have been seen for hospital treatment now are.

Persons who present for services at hospitals with anywhere from mild to profound developmental disabilities may be coming from their home where they live with parents, from community residential programs where they live with staff, or, in the case of mild mental retardation, from an independent living arrangement. In each instance, the person needs individualized services that are informed by their capacities. Especially important is the use of concepts and language the individual can comprehend.

Serving persons with developmental disabilities in the hospital has evolved in many different ways. In most hospitals, these individuals receive services in the same areas of the hospital as all others. There are certain disadvantages to this approach in that the essential skills to meet the needs of the population may be lacking. There are a few general hospitals that have specialty units to serve persons with developmental disabilities and even more state hospitals that do.

When the person with developmental disabilities presents for services at the hospital, it is most often due to unmanageable behavior. That is not to say that individuals with developmental disabilities do not become psychotic, depressed, or anxious; they surely do, and these conditions need psychiatric attention. However, a majority of persons dually diagnosed with a mental illness and developmental delays present because they can no longer be dealt with in the environment in which they live. Commonly the individual receives such diagnoses as impulse control disorder not otherwise specified, intermittent explosive disorder, or, if adolescents or younger children, conduct disorder or oppositional defiant disorder.

Persons with developmental disabilities should leave the inpatient setting with a functional analysis of the problematic behavior that permits the outpatient setting to follow through with treatment that will facilitate habilitation. Often this entails the use of behavioral interventions. All hospital treatment of persons with developmental disabilities entails close collaboration with the team of persons providing all outpatient and residential services. Collaborative treatment is essential in the hospital's achieving successful outcomes with this population.

Medical Comorbidities

Psychiatric disorders complicated by or complicating medical disorders are a common occurrence. Psychiatric services are often required when there is a diagnostic question related to mentation or mood; when a patient is too "out of control" or their behavior is so "inappropriate" that management of the patient is not going well on the medical or surgical services; when the medical or surgical practitioner cannot communicate with the patient or cannot obtain informed consent; or when there is an ethical question about the course of treatment.

There is perhaps no better example of the psychiatric hospital's role in treating persons with medical illness than HIV infection. There is a bidirectional relationship between severe mental illness and HIV infection; persons with psychiatric disorders are at higher risk of acquiring HIV, and persons who are HIV positive have increased rates of psychiatric illness. The interactions between disorders and treatments are myriad. Psychiatric disorders may impair judgment and heighten the risk of contracting HIV (e.g., mania in bipolar disorder) or lead more directly to increased risk (e.g., intravenous drug use). HIV can induce, both psychologically and by a direct effect on the brain, anxiety, depression, psychosis, and dementia. Antiretroviral medications can induce psychosis. Drug–drug interactions—drugs prescribed for HIV status, psychiatric status, and medical disorders due to HIV status—make treating the comorbid psychiatric disorders quite complex. Being HIV positive per se, the symptomatology of HIV, the psychiatric disorders that predated HIV-positive status, and the psychiatric disorders resultant from being HIV positive may all diminish compliance with both retrovirals and psychotropics.

The hospital plays a unique role in meeting the clinical needs of persons who are HIV positive. Although the general hospital is the mainstay of treatment for this population, the state hospital is not infrequently called on to provide care and treatment to symptomatic and nonsymptomatic HIV-positive individuals.

Although HIV infection has been used as an example, a comparable presentation could be made for scores of medical disorders. Some, such as systemic lupus erythematosus, temporal lobe epilepsy, and space-occupying brain lesions, are dramatic examples. On a more frequent basis, hospital-based psychiatric and medical services draw together to treat such conditions as cancer, renal failure, and trauma.

Psychiatry has known for over 150 years that individuals with SMI die younger than persons without these disorders. And the reason for this is still unknown. It is known that medical comorbidities can be significantly exacerbated by psychiatric medications. This is no better illustrated than metabolic syndrome in persons taking some of the second-generation antipsychotic medications. It behooves the inpatient psychiatrist to work closely with his medical colleagues in the hospital and other staff like dieticians and occupational therapists to create and monitor wellness programs for his patients.

A service that has become standard in many state hospitals is hospice care. These services are provided to the state hospital patient who has spent some time in the hospital and without the patient needing to be transferred to another facility or even to change units within the hospital. The advantages to the patient are many, but the fundamental advantage is the patient's ability to remain in a familiar environment with staff he is comfortable with. It is important to have the patient's informed consent or the guardian's if a guardian of the person is in place, for all services that will not be provided and those that will. Hospice care in the hospital works closely with families and significant others throughout the patient's stay to process bereavement and loss.

Deaf Individuals

In treatment as orally based as is psychiatric treatment, the clinical approach to persons who are deaf presents a unique set of challenges. Although in many states, deaf individuals who need psychiatric treatment secure that treatment within the hospital alongside all others with the addition of translation services, some states have a statewide deaf unit at one of its hospitals. Here, persons who are deaf can interact with staff without the imposition of a translator and can be in an environment that is sensitive to the deaf culture. There are very few private hospitals that offer this service.

The range of the hospital's roles in treating deaf persons is no different than for hearing persons. To fulfill that role, hospital staff needs to be aware of and sensitive to the deaf culture. For this population, the state hospital-based deaf unit may be the least restrictive, most integrated setting when inpatient treatment is required. In states with deaf units that also require civil admissions only come from other hospitals, this restriction is waived for the deaf population who can be direct admits from multiple loci of care, including general hospital EDs.

Forensic Patients

Persons admitted to the hospital pursuant to the commitment of a crime are the states' responsibility and one that the state generally fulfills directly at state hospitals. There are a few exceptions when the state contracts out for these services.

Forensic patients are in the hospital basically for one of three reasons: (1) pretrial, for a determination of competency to stand trial and/or of criminal responsibility for the crime; (2) after a finding of being incompetent to stand trial, guilty but mentally ill, or not guilty by reason of insanity; or (3) jail or prison could not manage the inmate due to his behaviors as a result of psychopathology. Restoration of competency to stand trial is a unique forensic task, and the hospital needs to have specialty functions to accomplish this. Much of the rest of the clinical treatment of the forensic population is the same as that of the nonforensic population. Security on forensic units is generally much tighter than in other places at the hospital.

Often the role that the hospital is required to fulfill for many forensic patients is one that it does not play very often for other patients—housing forensic patients for years to decades beyond the time the patient needs hospital-level care. The degree to which this occurs is heavily dependent on the state commitment statutes and procedural handling of its forensic patients.

Although there is a clear dichotomy between forensic and nonforensic patients based on the state statute under which the patient was admitted, the clinical variation and treatment need to show no such distinction. Whether a patient is civil or forensic, especially for minor crimes, has more to do with the circumstances of the patient's initial encounter with the police than it does with their clinical presentation. The boundary is also blurred these days because of states admitting more persons at the end of a criminal sentence, especially those convicted of sexual offenses.

The hospital has multiple roles with the forensic patient: (1) to meet the person's needs as a psychiatric patient, (2) to meet the state's needs to proceed with due process in trials, and (3) to maintain the public's safety in the face of those who break or are charged with breaking state or federal law. Hospitals are considerably more comfortable with the first role than with the other two.

With forensic patients, the judicial or quasi-judicial systems control the admittance and discharge of patients. In many states, this contributes to both overcrowding at hospitals and to an ever-increasing percentage of forensic patients in the hospital's census. It is an irony of current times that jails and prisons feel overwhelmed by inmates sheriffs believe should be psychiatric inpatients, and psychiatric hospitals feel overwhelmed by inpatients psychiatrists assess to need jails and prisons.

OTHER HOSPITAL ROLES

This section has focused on the inpatient functions of the hospital, which comprise the service that is unique to it. The hospital fills a number of other roles, many of which are also performed in some fashion by entities that are not hospitals.

Emergency Services

Psychiatric treatment is provided on an emergency basis in hospital EDs (see Fig. 56.3–1). The arrangements under which this is done vary greatly. In community hospitals, the person presenting with a psychiatric problem is generally treated in the same fashion as all individuals—the same waiting area, the same examining rooms, sometimes the same physicians. In larger hospitals, all of these functions are often segregated into a designated area of the ED where patients are seen by nonphysician evaluators who consult with psychiatrists who may or may not see the patient. Like many other hospital functions, crisis evaluation services have moved out of the hospital and to freestanding crisis services in some jurisdictions. Not uncommon is a hybrid model in which the hospital ED plays host to an outside crisis service. Here, the hospital performs medical screening evaluations.

The ED functions may include psychiatric holding beds, that is, the ability to keep a person in the ED for up to 23 hours, thus avoiding an admission. The ED may include crisis beds, a service allowing a short number of days that again avoid admission to the psychiatric unit. Crisis beds are another service the hospital shares with nonhospital settings such as CMHCs, which offer freestanding crisis beds.

Psychiatric patients “stuck” in ED’s awaiting transfer to an inpatient bed have become a nexus for consternation over inadequate inpatient beds. These patients can wait hours, days, weeks, or in some cases over a month, during which time little is done for them other than room and board in the ED. In August 2014, the Supreme Court of Washington State found (*IN RE the Detention of DW et al.*) it unlawful, under Washington’s involuntary treatment act, to board patients in EDs just because the appropriate evaluation and treatment facilities are overcrowded.

Only about half the states have processes in place to systematically identify open beds for psychiatric patients who need admission. Even those states that can effectively search for bed availability are stuck with the inadequate number of psychiatric beds nationwide. A 2012 study by the Treatment Advocacy Center, “No Room at the Inn,” demonstrated that not one state had sufficient numbers of public hospital psychiatric beds.

Step Down/Admission Diversions Services

Hospitals offer a range of services that function between inpatient and outpatient levels of care. Such services include day hospital, partial hospital, and night hospital. In treatment arrangements that are during the day, the individual attends a full day of active psychiatric treatment but lives outside of the hospital, for example, in their home, with family, or in a community residential program. In the night hospital program, the person leaves the hospital for school or work during the day but spends overnights at the hospital. All of these programs are also used as attempts at admission diversion, that is, to avoid inpatient hospitalization for this episode of illness. Step-down programs and admission diversion programs are also offered by nonhospital entities, with the latter also offering respite beds. These have a longer length of stay than crisis beds and are not generally provided by hospitals.

Partial hospital programs, once enthusiastically endorsed by insurers as less expensive alternatives to inpatient treatment for their use as both alternatives to admission and step-downs to decrease the length of stay, have lost favor. There is a dwindling supply of such programs. Just between 2000 and 2001, the number of facility members of the National Association of Psychiatric Health Systems (NAPHS) offering partial programs decreased from 83% to 67%. Between 2003 and 2013, the number of hospitals offering partial programs decreased by 20% (from 508 to 410). There is expected to be further loss of partial programs if CMS decreases their reimbursement rate, as it is proposing to do.

Outpatient

Outpatient services are offered in more settings than any other service. Besides the hospital, outpatient services are found in CMHCs; group settings, either integrated with primary medical services or at their own sites; private practices; family services agencies; and hosted in locations such as shelters, specialty clinics, mental health residential programs, and mobile units. Payment for these services is most often by third-party insurers—private or government—with a copay by the patient. In larger metropolitan areas particularly, some outpatient providers have established practices that take no insurance.

The major challenge facing outpatient psychiatry at hospital locations is the high cost of delivering the treatment within hospital settings and the poor reimbursement rates. It has reached the point where expanding business in the outpatient department (OPD) is the last objective of the hospital because each new patient adds to the deficit.

On a more practical note, hospitals are seen as unfriendly places to the individual seeking outpatient psychiatric services. Parking is often difficult, far from the OPD, and expensive. Negotiating the corridors of the hospital is a challenge that many would prefer to avoid. In addition, the patient may have to go through a registration process that simply adds another layer of annoyance.

The prognosis for hospital-based outpatient services is not good. Often the victim of cherry-picking by others (the most difficult patients are directed to the hospital OPD), the hospital psychiatric OPD is on the hit list of many hospital chief executive officers. One remedy may be hospital-based integrated clinics where outpatient psychiatry and medicine are collocated. Such attempts have been around for 40 years, but the momentum for such integration is accelerating.

Consultation-Liaison

Although many hospital executives would gladly replace the psychiatric inpatient service with more profitable medical-surgical beds and make much better use of the space devoted to the psychiatry OPD (which is often banished from the main hospital buildings anyway), the C-L function is usually highly valued. In part, that is because the C-L service directly affects the hospitals' medical and surgical services by evaluating patient's capacity to consent, assessing cases of delirium and psychosis, and assisting with difficult dispositions. The C-L service can be invaluable in making differential diagnoses that will fundamentally alter treatment and disposition. Some have argued that it is because a hospital could not effectively function without C-L psychiatry that much of the rest of hospital-based psychiatry is tolerated. This may be a somewhat cynical overstatement, but it certainly has some elements of truth. A well-functioning C-L service is a fountain of goodwill for the psychiatry department.

Community Education and Patient/Family Support

One role of the hospital that is largely one of goodwill is the hospital's role as host to a remarkable array of self-help and support groups. Those that fall under the penumbra of mental health and substance abuse activities are frequent in hospitals; such groups are Alcoholics Anonymous, Narcotics Anonymous, and the National Alliance on Mental Illness. Less directly related to mental illness but using principles of support are groups centered on all manner of chronic conditions and issues, such as breast cancer, colostomy, and scleroderma. There are also groups for individuals in specific life circumstances, such as parents without partners and parents who lost a child to cancer.

Hospitals also play a community education role. Members of the psychiatry staff may provide substantive lectures geared to the lay public. These are different yet complement the hospital's psychiatry grand rounds, which themselves are usually open to the public. Another form of education is informing the public about the services the hospital has to offer.

FUTURE DIRECTIONS

The challenges that face hospitals in the second decade of the 21st century are not new. Prior to 1950, virtually every problem and many of the solutions that define contemporary hospital psychiatry were noted in the professional literature. One need only read such sources as the *American Journal of Insanity*, *Alienist and Neurologist*, or state hospital annual reports to find them all.

Homelessness, the overpopulation of jails and prisons with persons with mental illness, the eschewal of persons with mental illness from any locale because that jurisdiction does not want financial responsibility for the person, an inadequate focus on treatment and overreliance on management, and a propensity to not spend tax money on persons with mental illness are all conditions Dorothea Dix found in the 1840s when she began her lifelong work of reform. Samuel Woodward, APA's first president and the first superintendent of what is now the Worcester Recovery Center and Hospital (see Figs. 56.3–4 and 56.3–5), would have recognized them all.

The loss of the person in meeting the acute needs of the patient, the reliance on modern technologies for diagnoses that have diminished one-to-one time with patients, and the general sense of the dehumanization of psychiatry and medicine, in general, were noted by William Allison White in 1925. White remarked in his APA presidential address that "the introduction of these highly technical methods has been accomplished by a corresponding lack in development, at least, if not actual loss, of any adequate dealing with the patient as an individual or as a human personality."

Even hospitals bending to the dictates of payers to minimize costs is not new. More than 125 years ago, Kirkbride lamented that "it will be a sad day for these institutions, and still sadder for the patients in them, when the rivalry of hospitals and their offices shall be, rather to discover for how little inmates can be kept, than to secure what is best, and most thoroughly promotes the great objects for which they were established."

State hospitals are disappearing by design. Whether that is the result of thoughtful or ill-conceived planning is a matter of debate. General hospital psychiatry programs, however, are disappearing through a thoughtless process of survival of the fittest.

Reimbursement and operating margins for psychiatric services lag behind those of other hospital-based medical services. The diminishing financial returns from psychiatry have led hospital management consultants to recommend converting psychiatric beds to higher-margin medical and surgical beds. Even to remain fiscally viable now, psychiatric hospital inpatient revenues need to cross-subsidize emergency, consultation, and outpatient services.

Today, psychiatrists generally fail to acknowledge those times when the psychiatric hospital is a forerunner or role model for the rest of psychiatry, if not the rest of medicine. One of the foci of contemporary medicine is the integration of medicine and psychiatry or medical and mental health services. As practitioners in psychiatry and in medicine focus on methodologies to integrate care and treatment, they need look no further than the public psychiatric hospital, which has been an integrated care organization for over 100 years and still is a fine example of integrated care and treatment. Outpatient integration, it seems, is mimicking business as usual at the state hospital but without its walls.

Attributes of a state hospital that contribute to its high degree of integration include:

- Psychiatric and medical services collocated
- An integrated psychiatric and medical treatment plan
- A single shared medical record, now an electronic medical record in many institutions
- Ease of communication among a patient’s physicians and between those physicians and other disciplines
- Case or care management integrated into treatment
- Professional and paraprofessional staff assisting patients to follow through with psychiatric and medical recommendations in an integrated housing and care model
- On-site wellness programs, for example, dietary, exercise, organized leisure
- Other health promotion activities, for example, weight loss, smoking cessation, treatment of substance abuse
- Transportation to any off-site medical appointments
- Workforce development, for example, student placements, pre- and postdoctoral internships, residency rotations
- Paid time off for staff education
- On-site dental, podiatry, optometry, radiology, phlebotomy, and neuropsychiatry services
- Peer supports
- Referrals to community and social supports
- Services for all independent of the ability to pay

- Funding supports not only direct service but time for collaboration
- Unitary billing system
- Transition services for relocation provided and funded
- Interfaces with vocational services
- Provision of in vivo training, for example, bus riding, banking, using the library
- On-site hospice care with direct care staff the patient is already familiar with.

The state psychiatric hospital, as an integrated care system, should have outcome measures that reflect these attributes. The current, common outcome measures fail to take this into account and currently include the number of assaults patient on patient and patient on staff; the number of serious assaults; the number of episodes and time in any form of seclusion or restraint (manual, mechanical, chemical); two or more antipsychotic medications at discharge; five or more psychiatric medications prescribed; time out of the hospital on unsupervised passes; and timeliness of all manner of documentation. Many of these measures are open to interpretation, especially what a facility chooses to label as an episode of restraint. What about improvements in health and wellness as outcome measures?

Virtually no knowledgeable commentator claims that the system of care and treatment for mental illnesses can be sustained without the roles played by psychiatric hospitals. At the same time, too few informed people are working on methods to interdigitate the hospital's roles into the fabric of an integrated system of care, one that looks less like Figure 56.3–1 and more like one that achieves effective outcomes, through a person-centered approach, with fiscal management that does not compromise the very care and treatment psychiatrists are attempting to deliver.

56.4 Mental Health Services Research

Lisa B. Dixon, M.D., M.P.H., and Milton Wainberg, M.D.

The imperative for mental health services research arises from some basic and alarming facts. Over half of the persons with mental disorders receive no mental health treatment. For those who do, the vast majority—approximately 75%—do not receive treatment that can be judged of good quality by evidence-based standards. Those outside of the health services research field, such as clinicians and other stakeholders, may not see how mental health services research can improve the substandard quality of mental health care. In fact, they may not even understand what health services research is. The Association for Health Services Research broadly defines it as:

> Implementation Science is the multidisciplinary field of scientific investigation that studies how social factors, financing systems, organizational structures and processes, health technologies, and personal behaviors affect access to health care, the quality and cost of health care, and ultimately our health and well-being. Its research domains are individuals, families, organizations, institutions, communities, and populations.

This chapter reviews the specific scope of mental health services research and illustrates through several case studies how such research addresses critical questions that arise in the routine provision of services, laying the groundwork for improving the quality of mental health care.

Notably, implementation science or the study of strategies and approaches to promote the use of evidence-based practices has become a key element of mental health service research.

THE SCOPE OF MENTAL HEALTH SERVICES RESEARCH

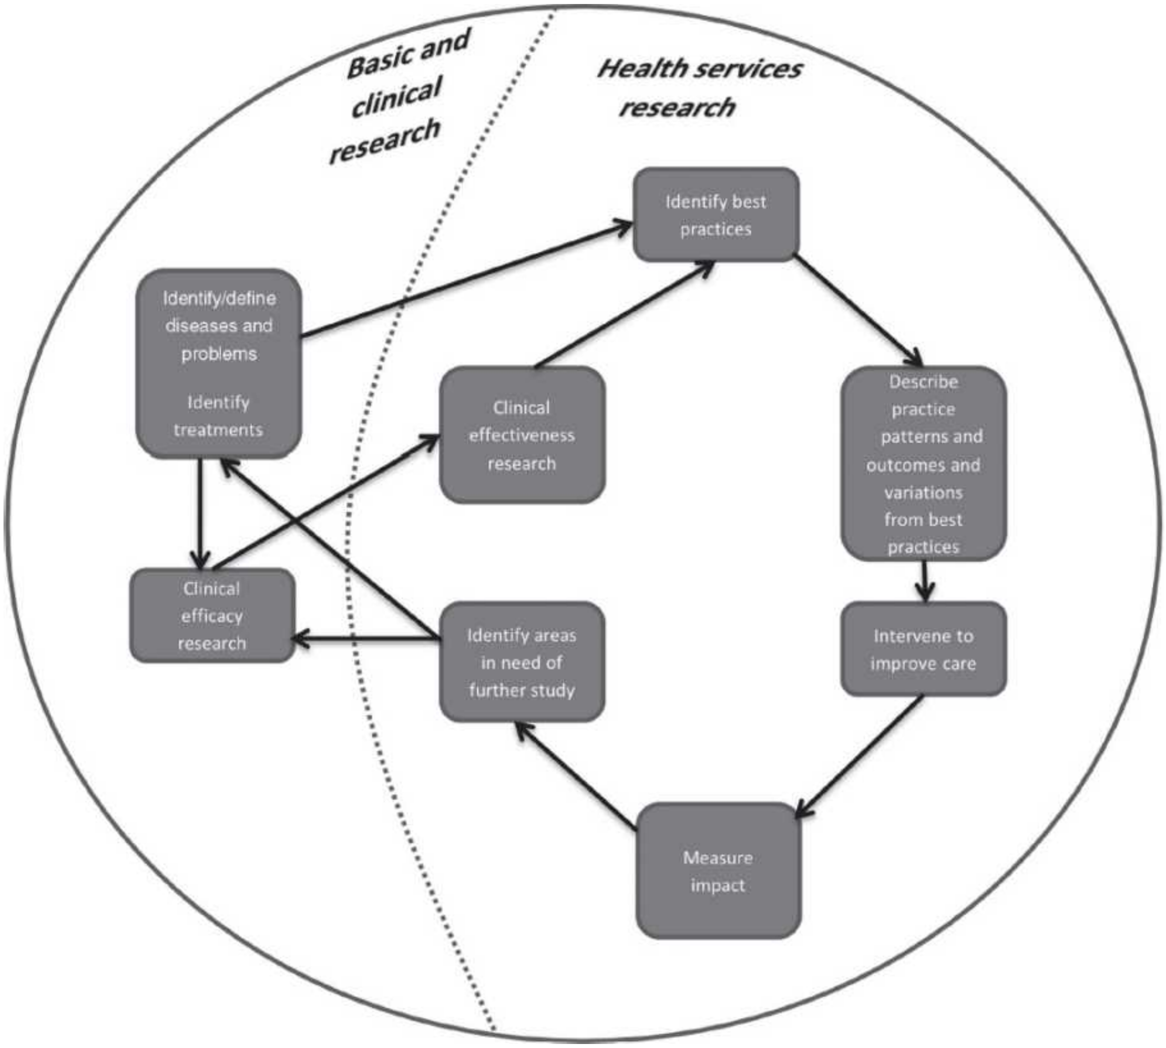
Clinicians seek to address identified clinical problems, disorders, and diseases. Clinicians turn to biomedical research to answer two basic questions: (1) What is known about the nature of this problem? (2) What can be done to remedy it or alleviate the suffering associated with it? Research answers to the first question derive from *basic sciences research*, whether biologic (e.g., What neural pathways are affected in bipolar disorder?), behavioral (e.g., How do organisms respond to different types of reinforcement schedules?), psychological (e.g., How do negative automatic thoughts affect mood?), or sociologic (e.g., What are the pathways to homelessness?). Research answers to the second basic question arise from *clinical research* involving well-controlled treatment trials designed to determine efficacy and safety, as well as from the more or less systematic trial and error of clinical experience. Broadly, the basic and clinical sciences deal with the knowledge needed prior to the initiation of routine care. In other words: What is the health problem, and what treatments might relieve this problem? *Health services research* questions, however, arise once clinical services get underway. Clinicians have extensive exposure to the basic and clinical sciences during their training but may have little or no exposure to, and hence little understanding of or appreciation for, the value of health services research and implementation science.

What kinds of questions do mental health services researchers ask? These questions can be divided into two general categories—*clinical services research* and *service systems research*. Like clinical research, *clinical services research* focuses on “front-line” clinical issues and uses individual service recipients (patients, families) as the participants and units of study. Examples of questions asked by *mental health clinical services research* include the following: How effective are antidepressant agents in producing illness remission among typical patients with major depression seen in routine office practices? What considerations influence individuals to seek treatment and to agree to complete a course of prescribed treatment? What range of treatments for persons with schizophrenia are “evidence-based?” Do persons with substance abuse and mental illness have better outcomes when they receive care from integrated addiction mental health teams or programs with parallel services? What are the effects of a routine depression screening measure in primary care on detecting and treating major depression in such settings?

Mental health services system research examines questions at the service system level and typically uses aggregated service components (providers, treatment agencies, state mental health systems, etc.) as the units of study. Examples of questions asked by service systems researchers include the following: How many persons with severe mental illness who are being treated in a public mental health system have access to routine primary care? Does this differ between two states with different Medicaid policies? What are the various sites in a city where homeless persons with severe mental illnesses receive services and are these coordinated? What are the effects of a decision by Medicaid to cap the total number of prescribed medications that recipients can receive? Do restricted formularies for antipsychotic medications reduce overall costs? Do they affect quality? Do local mental health authorities improve coordination, continuity, and quality of care for high-need patients?

Implementation science research typically integrates multiple levels to ask how to best implement evidence-based practice.

Given this broad scope of mental health services research, it is also helpful to note what it does not include (Fig. 56.4–1). The distinction has already been mentioned between basic and clinical research on one hand and mental health services research on the other. The interface between clinical research and clinical services research begins at the transition between treatment efficacy and treatment effectiveness studies. *Efficacy studies* examine the outcomes of treatments within narrowly defined samples of patients who are carefully selected to control for variables that might interfere with determining a treatment effect (e.g., the exclusion of patients with comorbid substance abuse or medical disorders). Efficacy study designs attempt to maximize internal validity. *Effectiveness studies* examine treatment outcomes among more inclusive, diverse, and “typical” clinical populations. External validity assumes a more important role. Generally, effectiveness studies only occur after treatment efficacy has been established. Mental health services research, while somewhat distanced from the efficacy studies with which many clinicians are familiar, is still *research*, using standardized scientific procedures to answer specific research questions to generate new knowledge that is generalizable beyond the system being evaluated. It should be distinguished methodologically from routine activities undertaken by service systems and service agencies to monitor policy implementation, program or system administration, or quality assurance.



Basic and clinical research
Health services research
Identify best practices
Identify/define diseases and problems
Identify treatments
Clinical effectiveness research
Describe practice patterns and outcomes and variations from best practices
Clinical efficacy research
Identify areas in need of further study
Intervene to improve care
Measure impact

FIGURE 56.4–1. The relationship between basic and clinical research and health services research.

Figure 56.4–1 illustrates the distinction between basic and clinical research and health services research, the flow between these larger research domains, and depicts various activities conducted within health services research. For example, one way in which clinical practice is affected by services research occurs as the results of clinical efficacy trials and effectiveness trials are applied to routine practice—a form of "translational research." Given that a primary goal of basic and clinical research is to inform clinical practice when a body of scientific knowledge has accumulated, it should be adopted into clinical practice. However, this translation does not happen as it should; the gaps between existing scientific knowledge about treatment efficacy and effectiveness on one hand and routine clinical practice on the other have been referred to collectively as the "quality chasm" in medical care encompassing both access and quality.

A major question for mental health services research, then, is how to promote the adoption of scientifically validated treatments (evidence-based practices) and, by doing so, bridge the "quality chasm." One response has been the development of evidence-based practice guidelines, variously referred to as evidence-based practices, evidence-based treatment recommendations, or "best practices." The identification of evidence-based best practices is critical to examining current practice patterns, evaluating their quality, identifying areas in need of improvement, and ultimately identifying areas in which current treatments fall short. The methodology for developing such evidence-based practice guidelines emphasizes the results of efficacy and effectiveness research, augmented by expert opinion when research evidence is underdeveloped in essential areas.

Once a set of research-based best practices has been identified, health services researchers can ask a variety of questions about how current practices compare to best practices, including variations in practices across treatment settings, practitioners, and patient subtypes, as well as the relationship to such factors as insurance coverage, health policies and regulations, and cultural diversity. Such research can also examine patterns in outcomes of care across different kinds of services and relate these to patterns in the implementation of evidence-based practices. Such studies are essentially descriptive, but they allow comparisons of actual practices to standards of care.

Identifying gaps between actual and best practices can lead to developing health services interventions to improve care. Such interventions fall into one of two general categories. *Supply-side* interventions focus on individual providers or service programs. These interventions seek to change the care offered in some way. Some examples of supply-side interventions include provider education and training programs, systematic feedback to providers regarding their current practices, consultations to agencies about the implementation of best practices, financial incentives to alter practices, and so on. *Demand-side* interventions focus on the demand for services and are directed at changing patient behavior. Examples of such interventions include educating patients about best practices, training patients in how to advocate for themselves in health settings, and providing service vouchers to patients to enable them to select services that they identify as most helpful.

Both supply- and demand-side interventions can occur at distinct levels involving individual providers and patients, local service agencies, local or regional service systems, and local, regional, or national policies. *Shared decision-making* is a strategy that involves both supply-side and demand-side approaches at the level of the individual patient–provider interaction. *Policy-level interventions* occur at the level of a system of care with the intention of changing patterns of service delivery—for example, changing the services covered by insurance, creating local mental health authorities to improve the coordination and outcomes of treatment in a given locale, mandating the integration of mental health and substance abuse services, or offering Medicaid care through a coordinated and managed “health home.”

Such interventions, however, are not in themselves health services research. Rather, health services research evaluates the effects of such interventions on a range of outcomes, including patient outcomes, changes in patterns of care, and costs. In health services research, the interventions must be clearly defined, the fidelity of their implementation closely monitored, and the outcomes measured in a standardized form. Research designs to minimize threats to internal and external validity—for example, randomized clinical trials—are critical, as in clinical research. The research questions, although based on specific interventions, focus on knowledge that can be generalized to other settings. As in other areas of research, findings from any phase of health services research optimally feedback to raise new research questions.

Recent work has focused on methodologies for implementation research, a burgeoning domain of health services research that attempts to understand how effective interventions can be implemented. Studies of implementation problems in carrying out interventions at the level of systems or individual clinical care depend upon various conceptual frameworks but generally acknowledge the need to study factors including (1) the structural, political, and cultural context as well as internal organization of the settings in which the intervention will take place, (2) characteristics of the individuals involved, (3) the process of implementation of the intervention, and (4) the nature of the intervention itself. Such research takes a pragmatic approach, seeking to understand how real-world conditions affect the implementation of the evidence-based practices for which clinical and other research has established evidence of efficacy and effectiveness.

The following “case reports” concretely illustrate the application of mental health services research to critical questions that arise in the routine provision of services.

Case 1: Treatment of Depression in Primary Care Settings

Depression is one of the most common mental disorders and accounts for a staggering amount of disability worldwide. Over the last several years, there have been substantial improvements in methods for diagnosing depression, and a broad range of efficacious treatments for depression exist, including antidepressant medications and evidence-based forms of psychotherapy. A number of evidence-based practice guidelines have been developed, so the opportunities to effectively diagnose and treat depression are substantial.

Given the state of diagnostic and treatment methods for depression, how successful is the United States in treating depression? This health services research question raises some basic epidemiologic queries. How many people suffer from depression? Do they seek treatment, and where? What treatments do they receive? The most comprehensive estimates of the prevalence of mental disorders derive from the Epidemiologic Catchment Area (ECA) Study and the National Comorbidity Survey (NCS), which estimated the 1-year prevalence of major depressive disorders at 6% to 7%. The vast majority of depressed individuals (about 80%) contact a health care provider over a 1-year period, but only about 25% receive any appropriate treatment for depression. Most patients (about 80%) who visit a health care provider for depression see a primary care provider; only about 20% of patients with depression visiting a health care provider see a mental health specialist. Among such patients with a treatment contact for depression, 80% of those treated in primary care received no appropriate treatment for depression (pharmacotherapy or counseling). The opposite prevailed in mental health treatment settings, where most patients (nearly 90%) received an appropriate form of depression treatment. Such data illustrate the challenges in providing quality care for individuals with depression. Most persons receive no depression treatment (despite some contact with a health care provider). Most of those who do receive some treatment receive inadequate care. The predominant opportunity for the treatment of depression is in primary care. How can clinicians and administrators address these problems in access to and quality of depression care? How can mental health services research assist in these efforts?

Health services researchers have examined interventions targeting providers (the supply-side of care), individuals affected by depression (the demand-side), and policies. By far, the majority of health services research in this area has focused on the supply-side through attempts to change provider management of depression, especially primary care providers, who see most of the patients with depression. Such research has approached the under-treatment of depression in primary care with different interventions of interest. For example, a multicomponent health care system–level intervention called “collaborative care” structures depression treatment in primary care settings by using case managers who educate and follow patients, track outcomes, and adjust treatments for patients who are not responding, consultation and decision support for primary care providers by mental health specialists (psychiatrists or psychologists), and the use of technology-based resources to support the system. Numerous randomized controlled trials on collaborative care for depression have demonstrated meaningful effects on depression symptom improvement, adherence, response to treatment, remission, and recovery from depression, as well as satisfaction with care. However, only a small effect has been established on patient quality of life, including functional status.

A second health services research approach has studied the implementation of quality improvement (QI) programs for managed primary care settings with the goal of increasing the percentage of clinically depressed patients receiving appropriate depression care by national guidelines. The QI intervention consists of four components: institutional commitment of in-kind resources, training of local clinical leaders to implement interventions (cognitive behavior therapy, pharmacotherapy), training of local treatment staff, and patient identification. In one 12-month study, depressed patients in QI intervention clinics were more likely to receive counseling or medications, visit a mental health specialist, have a remission from the depressive episode, and retain employment than depressed patients in “control” clinics. Researchers have evaluated another approach in “behavioral health labs” that improves screening and detection of depression in primary care settings. All three of the above depression treatment models demonstrate the potential for improving depression care in primary care settings through “supply-side” interventions. Major challenges remain, however, in promoting the widespread adoption of these approaches.

Far less research on depression care has been conducted on demand-side interventions with patients, although one can certainly argue that even the predominantly supply-side interventions just reviewed increase demand by educating patients about their symptoms of depression and about the value of treatment. Negative attitudes about depression and its treatment among the general population can deter persons from seeking help. Such negative attitudes arise from personal health beliefs, social norms, and stigma, as well as from prior negative experiences with help-seeking. True demand-side interventions are aimed at directly increasing the likelihood that individuals with depression will seek and participate in effective treatment. Such demand-side interventions focus on awareness of the signs and symptoms of depression, self-assessment for these signs and symptoms, the effectiveness of treatment, and skills in seeking help. Some common examples of such efforts include National Depression Screening Day campaigns, free depression screenings at employee health fairs, free pamphlets in physician offices and clinics, antistigma campaigns through the media, and direct-marketing media campaigns on depression, such as those currently put forward by pharmaceutical companies. Health services research that examines the effects of such programs remains sparse, and little is known about the effects of these types of demand-side interventions.

A third domain of intervention to improve detection and treatment for depression in primary care is that of policy, system organization, and financing approaches. A prime example of this type of intervention is the current effort to promote health insurance parity for the treatment of mental disorders. Inadequate insurance coverage for the treatment of a mental disorder poses major barriers to treatment. The federal Affordable

Care Act (ACA) enacted in 2010 expands coverage of mental health and substance use disorders by including benefits for such disorders in the Essential Health Benefits required of all new small group and individual market insurance plans and by applying federal parity protections more broadly, requiring insurance plans to cover treatment for mental health and substance use disorders at parity with medical and surgical benefits; a projected 62.5 million individuals will benefit by access to these federal parity protections. In addition, the ACA provides states a new option for organizing care in their Medicaid programs: “health home” services for Medicaid beneficiaries with severe chronic conditions who can benefit from enhanced coordination and management of physical and behavioral health care as well as long-term community-based services and supports. The “health home” model aims to improve the quality of health care and the patient experience while providing more cost-effective care. Health services research on service organization and financing seeks to answer critical questions about the effects of policy interventions such as parity laws and “health homes” on issues including the quality and experience of behavioral health care—such as depression care—delivered through reorganized systems.

Case 2: Services for Families of Persons with Schizophrenia

During the second half of the 20th century, clinical research on families in the treatment of individuals with schizophrenia dispelled early assertions that disturbed family relationships play a major role in the etiology of the disorder. Instead, research led to the recognition that families provide major support networks for most persons with this disorder and that they need education and support to enable them to engage as partners in care. The potential advantages of engaging and educating families optimally were suggested by early studies linking high levels of “expressed emotion” among families to a greater likelihood of patient relapse after hospital discharge. Research spanning from the 1970s to the 1990s clearly established family psychoeducation (FPE) as an evidence-based practice in the care of individuals with schizophrenia. The Schizophrenia Patient Outcomes Research Team included FPE as a treatment recommendation, stipulating that patients who have ongoing contact with their families should be offered a family psychosocial intervention that lasts at least 9 months and includes education, support, and some training in problem-solving skills. Other statements of best practices also include a recommendation for FPE. FPE was found to reduce relapse rates, improve medication adherence, reduce symptoms, and improve functional outcomes for individuals with schizophrenia. Specifically, more than 30 randomized clinical trials showed that relapse rates for individuals receiving FPE were 25% to 50% lower than those observed for individuals receiving standard individual services.

In line with the health services research framework (see Fig. 56.4–1), investigators have examined the prevailing patterns of practices as they relate to families with regard to both access to any services and, more specifically, access to evidence-based practices consistent with the FPE model. A variety of studies conducted in community settings and in Veterans Administration facilities has shown that not only is FPE rarely offered, but in fact, a far lower standard of family contact with clinicians occurs in the majority of cases. Chart reviews, clinician interviews, and consumer interviews all have produced the same conclusions. Thus, major problems in the access to and quality of family-oriented services exist.

Following the health services quality-of-care framework, researchers have undertaken efforts to improve practices by disseminating FPE. Supply-side approaches have been the most common. Numerous initiatives to disseminate FPE have been attempted throughout the country. The New York State Office of Mental Health (OMH) mounted an impressive effort to implement programs at 35 different sites throughout the state and provided extensive training. Although numerous family groups were started and the potential benefit was large for those families and patients who participated, OMH decided not to continue the project because only a small number of families and patients throughout the state actually received the program. The Substance Abuse and Mental Health Services Administration included FPE as part of an effort to disseminate evidence-based practices by creating toolkits that include informational resources for all stakeholders, a workbook for practitioners, and a fidelity scale. The implementation phase of this project resulted in a limited selection of FPE as a practice to disseminate and limited penetration of FPE in those sites that selected FPE.

The marginal success of these dissemination initiatives for this evidence-based practice demands a greater understanding of how to influence changes in practice. Research must strive to understand and overcome observed roadblocks to the dissemination of family services, whether these roadblocks exist on the supply-side among providers and service systems or on the demand-side among patients and their families. Such roadblocks can take many forms. In identifying such barriers, health services researchers seek critical points for intervention to improve dissemination. For example, practitioners may be unaware of the value of the intervention, or they may lack the skills to deliver it. Families may be suspicious of such services as a result of unpleasant experiences based on older family therapy models. Payment systems may not provide support for the programs. However, even the FPE demonstration projects that had the capacity to overcome most or all of these barriers failed substantially to affect dissemination. In such a case, health services researchers have at least two other strategies at their disposal. The first is to develop more inventive dissemination strategies. The second is to decide that a modified or new evidence-based practice is needed—one that is more acceptable to providers, patients, and service systems.

This first task of developing more inventive dissemination strategies requires reevaluating the barriers to dissemination. Such barriers exist at the disparate levels of patient and family, providers, administrators, and payers. Supply-side strategies, such as providing higher rates of reimbursement for providing FPE, as well as more intensive and targeted training for providers, could be successful. Health services researchers investigate these strategies by using qualitative methods to interview providers and payers where FPE initiatives have already been started to determine whether they think that increased rates of payment or training would help. Strategies under study also target barriers to FPE at the consumer and family levels, thus focusing on developing the demand for FPE. A new approach called Recovery-Oriented Decisions for Relatives' Support (REORDER) uses a shared decision-making process to structure patients' exploration of whether they want to include families in their mental health care. REORDER is personalized by attending to patient preferences for family involvement, focusing on the mental health recovery goals of the patient, and exploring how family members could join with the patient to meet those goals. The REORDER clinician begins by working with the consumer to identify the pros and cons of family involvement and then uses education, support, and decision-making exercises to assist and empower patients to meet their goals. A randomized trial showed that this approach markedly increased rates of family contact with clinicians while it also increased a measure of recovery among participants assigned to the REORDER condition.

The second strategy to address difficulties in implementing FPE is to develop new evidence-based practices or to test revised models of FPE that attempt to reduce barriers to implementation. For example, a meeting of family researchers and practitioners identified the need to determine the critical ingredients of FPE so that a simpler and briefer model could be tested. The National Alliance on Mental Illness (NAMI) Family to Family Education Program may provide a second approach. This program is not a clinical service but is peer-driven. Trained family-member volunteers teach this manualized 12-week program in weekly 2- to 3-hour sessions. The program provides information about mental illnesses, treatments, medication, and rehabilitation. Participants also learn self-care, mutual assistance and communication skills, problem-solving strategies, and advocacy and develop emotional insight into their responses to mental illness. Although the program does not aim to reduce patient relapse, it may provide some benefits to families. Notably, the program had been widely disseminated in spite of the dearth of systematic research demonstrating its effectiveness. After its dissemination, a partnership between health services researchers and NAMI conducted three sequential studies, including a randomized trial have provided evidence that the program is helpful to families—in improving family functioning, coping, empowerment, and knowledge. This demonstrates that in the pursuit of dissemination of evidence-based practices, health services researchers may tackle the challenge of conducting research on existing practices that are in wide use but as yet relatively unstudied.

Case 3: Addressing the Burden of Mental Illness and Mental Health Disparities Using Technology and Implementation Science

Burden and Treatment Gap. Since the 1990s, we have been aware that mental and substance use disorders (henceforth, mental health and/or disorders) are the largest contributor to the global burden of disease everywhere. This problem will persist as long as a minority of individuals with mental and substance use disorders never receive treatment. This treatment gap is vast and global. In high-income countries, 35% to 50% of people in need of mental health care do not receive care. Despite being home to more than 80% of the world’s population, low- and middle-income countries have less than 20% of the world’s mental health resources. On average, only 0.5% of national health care budgets in low- and middle-income countries (vs. 5.1% in high-income countries) are devoted to mental health care, and 75% to 85% of those with mental disorders in low- and middle-income countries have no access to care. Mental health disparities exist everywhere, and the majority of those in need of mental health care worldwide lack access to high-quality mental health services. Stigma, structural discrimination, human resource shortages, fragmented service delivery models, and lack of research capacity for implementation and policy change contribute to the current mental health treatment gap.

Shortage of Humans Resources/Task shifting. One of the most significant challenges in decreasing the mental health treatment gap is the significant scarcity of trained mental health workers in health care systems worldwide. The shortage of certified mental health specialists is vast and global, especially those who are skilled in using evidence-based practices. "Task-sharing or task-shifting"—the process of delegation whereby clinical tasks are moved from a highly specialized workforce to less specialized health workers, including trained lay health workers—is an effective strategy to deal with the mental health personnel shortage and is a great option to enhance efficiency on delivery of health care services. Multiple studies throughout the world have proven that lay health workers can effectively provide evidence-based treatment for common mental disorders. Task sharing requires a significant, ongoing role for psychiatrists and psychologists to properly train, continually supervise, ensure quality assurance, and support for the nonspecialist health workers.

COVID. Globally, the already limited access to mental health services has worsened as health care systems prioritize COVID-19 care. People with mental disorders are highly vulnerable to Coronavirus 2 (SARS-CoV-2) infection and vice versa. History of psychiatric illness is a risk factor for COVID-19 infection, hospitalization, and death. COVID-19 survivors have elevated rates of depression, anxiety, psychosis, PTSD, mania, and sleep disorders. It has exacerbated the structural, social, economic, health, and mental health vulnerabilities of disadvantaged populations both in the United States and globally (e.g., racial/ethnic minorities, migrants, and displaced people, low socioeconomic background), placing them at elevated risk for COVID-19 and its consequences, including increased mental health service needs.

Telehealth became necessary to protect providers and patients against SARS-CoV-2 infection and maintain ongoing care for patients already receiving care or new patients. However, health care systems struggle to make these transitions in providing care. Developing remote-based methods to triage and provide mental health services became crucial. Importantly, wherever this became available via phone or internet, patients previously in care with access to resources and digital infrastructure were more easily adherent to care, as some of the limitations to access to care could be addressed (e.g., travel, childcare, work, school). Unfortunately, the mental health services access for new patients or those without resources was negatively affected. The COVID-19 pandemic calls for a new model of mental health service delivery in a system that was already incompetent to provide mental health care.

Comorbidity among psychiatric diagnoses is the rule rather than the exception. It produces greater functional impairment and worsens social determinants. Both psychopharmacology and/or evidence-based psychotherapy trials have shown efficacy and effectiveness in high-, middle-, and low-income countries, suggesting that both modalities have promise in expanding treatment for mental disorders where services are scarce. Yet, to date, studies integrating mental health in primary care (e.g., Collaborative care) address one or two disorders through individual-level interventions and show low enrollment of racial/ethnic minorities and underserved populations. Decreasing mental health disparities necessitates sustainably implementing comprehensive mental health services for multiple disorders through community-health systems-policy makers partnerships, which in turn can improve functioning and social determinants and inform new policies.

Technology. Leveraging novel technology to support the implementation and supervision of evidence-based treatments can help meet mental health needs. Digital technology in the mental health sector has proliferated globally. Digital patient and provider-facing solutions can give unprecedented access to high-quality mental health care and can effect scalable, cost-saving, reliable, and sustainable, comprehensive mental health services delivery, especially in low-resource settings, yet they are seldom used with disadvantaged communities and public health systems. Digital technology can improve overall cost-effectiveness by strengthening the mental health capacity of existing nonspecialists and supporting task-shifted delivery of high-fidelity evidence-based treatments.

Closing the Gap—Implementation Science. The gap between mental health evidence-based treatment research and practice in real-world communities and health systems is vast; less than half of clinical innovations make it into routine practice. Reasons include the fact that researchers tend to disseminate their work through traditional academic conferences and publications. Further, the research settings where researchers develop and test evidence-based treatments do not reflect the complex, less-resourced real-world settings in which they ultimately must be delivered to have a population impact. Dissemination and implementation science address this research-to-practice gap aiming to accelerate the speed with which translation and real-world uptake and impact of testing, evidence-based treatments occur and improve public health. Meeting the population's mental health needs requires employing implementation science methods to integrate evidence-based treatments into routine practice. Importantly, solutions implemented in low- and middle-income countries can offer innovative options that might be applied to improve mental health services across diverse settings worldwide, including high-income countries.

Two ongoing NIMH-funded studies, one in a low-income country, Mozambique, and another in New York City, address these challenges and needs using a stepped-care approach to improve clinical outcomes—symptoms, functioning, quality of life, among patients with any mental disorder guided by the Proctor's implementation framework. The framework asserts that implementation outcomes serve as necessary preconditions for attaining subsequent desired changes in service or clinical outcomes and that clearly distinguishing implementation outcomes from treatment effectiveness is critical for transporting interventions from research settings to practice. The two studies examine three distinct yet interrelated outcomes—implementation, service, and patient outcomes—to determine the overall system-level impact of implementing stepped-care comprehensive mental health services. Certain implementation factors, such as acceptability, appropriateness, and fidelity to the approach, are more salient early in the implementation process and may be leading indicators of reach, retention, sustainability, and cost, the most important implementation outcomes. The extent to which services are safe, effective, patient-centered, timely, efficient, and equitable as they are being implemented ensures the quality of care that fosters better clinical care and outcomes and patients' satisfaction. Ultimately, sustainability is the goal.

Both studies evaluate implementation, service, and patient outcomes using a digital platform, the Mental Wellness Everywhere Digital Training and Services Platform (mWell Everywhere), to create digital patient records, screen for all mental disorders and suicide risk using a validated ultra-brief screening (3 items) and triage (10 items) Mental Wellness Tool (mwTool), and guide task-shifted evidence-based treatment delivery with fidelity while monitoring clinical, services and implementation outcomes, and tracking individual and community-level social determinants. The instrument developed in Mozambique combines valid measures and has been tested elsewhere to comprehensively assess all psychiatric disorders and the severity of the illness to guide triage and treatment. The 3-item screener with proxy respondents detects any mental disorder among household relatives, thus allowing for further community reach. This permits efficient and convenient community assessment—an informant can identify with three questions the need to assess a family member living in the same household. Me-Well meets COVID-19 safety requirements (e.g., telehealth); and provides psychosocial support, self-help, and guidance to communities and providers. Using Me-Well, patients with common mental disorders (depression, anxiety, PTSD) receive Interpersonal Counseling, four structured sessions designed for use in nonspecialist settings, and focusing on the relationship between interpersonal problems (e.g., disputes, life changes, grief, loneliness) and the onset of psychiatric symptoms. For patients with severe mental disorders, providers use a tablet-based Medication Diagnostic Algorithm to deliver psychopharmacologic treatment according to specific diagnoses. For treatment of patients with substance use disorders, providers use Screening, Brief Intervention (Motivational Interviewing), and Referral to Treatment (SBIRT), a brief, one to four–session therapeutic approach that employs empathic listening to explore patients' goals, resolve ambivalence, and elicit motivation to change. Patients with moderate to high risk of suicide work with the provider to develop a suicide Safety Plan Intervention (SPI) that includes identifying warning signs, coping strategies, and sources of support to alleviate a suicidal crisis when hospitalization is not clinically indicated.

All of these evidence-based treatments have mobile applications that guide facilitators in standardized treatment steps and allow remote monitoring of patient outcomes and treatment fidelity. The Me-Well Everywhere platform guides and supports providers using interactive methods, knowledge tabs with tips and sample scripts, and automated processes to enable both supervisors and providers to recognize clinical “red flags” or fidelity issues. Meta-data from the platform tracks treatment fidelity and individual provider platform uptake implementation outcomes, for example, number of patients seen, the degree to which key activities are completed, and the average number of sessions per patient. Any user data that appears to deviate from the standard sequence of activities is automatically flagged for the supervisor to intervene and provide corrective feedback to the provider. The platform generates a detailed clinical record after each encounter and can communicate with any Electronic Medical Record platform to enable access to patient characteristics and medical needs (e.g., pregnancy, multimorbidities, current medications).

Implementing Me-Well Everywhere in Mozambique will expand the current mental health system that currently only provides access to care to the 30% of the population living in urban areas. In New York City, like in many high-income countries, shortages in mental health resources and how services are rendered create long waiting periods with the ultimate expectation of ongoing rather than evidence-based, time-limited treatment, requiring expansion of human resources to increase access. In reality, more than half of patients who are able to access mental health services drop out of care after 3 to 6 sessions, unrelated to symptomatic improvement. Thus, can we meet people where they are and provide indicated and tested treatment within that brief time frame by using short-term, evidence-based treatments, and reassessing the need for more care, and offer sequential treatments accordingly. Evaluating how to provide services with a more efficient approach using sequentially targeted and tested short-term treatments with proper follow-up assessment to determine the need for continued services may inform solutions to increasing access to those in need waiting for care.

Mental health disparities are associated with social determinants and substantial individual, familial, and community-level suffering. The public health system is yet to address the population's mental health and social determinant needs, which in turn worsen mental health and functional outcomes at the individual and community level. Systems of care must tackle all mental health disorders, especially when comorbidities are the norm. However, the scarce siloed mental health resources are insufficient to address these mental health disparities. Health care systems require integrating comprehensive mental health services, implementing brief, valid community, and individual screening approaches, and evidence-based treatments with fidelity. Principles of implementation science provide a road map for how to do so sustainably and inform needed policies to address the vast mental health treatment gap globally. Implementation of evidence-based treatments demands expanding the mental health workforce using task-shifting by rigorously training and supervising human resources with diverse training backgrounds. A multilevel transformative integration of evidence-based, comprehensive mental health services stepped-care leveraging rigorous technologies into health systems in partnership with the affected communities and policymakers can meet these challenges, ensure sustainable, comprehensive mental health services with associated policies to decrease mental health disparities, and improve communities' functioning and social determinants.

OVERVIEW

Pressures are mounting to ensure that the fruits of biomedical research translate into treatments and services. Mental health services research has substantial power to both inform and advance this process. In the end, all mental health services research can be summarized in three questions. Do all persons with mental health needs have access to treatment? Is the treatment they receive of adequate quality, incorporating the latest in scientific knowledge? Does the treatment offer good value—that is, good outcomes for the resources expended? These questions are posed by the field in such a manner as to maximize generalizability and to identify subgroup variations and needs. These questions must also be asked within systems concerned with health care equity and social policy to inform clinical care and maximize the benefit to all individuals—the ultimate goal.

Mental health services research, necessarily interdisciplinary, must consider how social factors, structural barriers, financing systems, organizational structures and processes, health technologies, and personal behaviors affect access to health care, the quality and cost of health care, and ultimately health and well-being. Health services researchers work closely not only with biomedical colleagues but also with investigators from other scientific disciplines (sociology, anthropology, psychology, economics, education, and political science) and with service system and policy leaders to implement and evaluate changes.

Much of biomedical science tends to be occupied with internal validity—the strength of the claim that the experimental manipulation causes the outcome. This leads to the desire to control all potentially confounding variables, but it reduces external validity. External validity, or generalizability, lies at the center of the translational process and health services research. At the same time, generalizability encompasses sensitivity to variations among subgroups of patients, taking into account demographic and cultural differences in disease, health care beliefs, and behaviors and access, as well as how health systems address barriers and leverage facilitators of services implementation.

Moving forward, mental health services research faces several challenges. First, while the advance of “evidence-based practices” embodies the principle of translating scientific knowledge into practice, more attention must be given to the complementary principle of “practice-based evidence.” In essence, how can one inform the directions of science through evidence that emerges from clinical practice and experience? Second, challenges for treatment systems and for researchers seeking to identify and promote “best practices” arise from the growing diversity of U.S. culture. Third, the field needs a better understanding of how to implement system changes and disseminate best practices. For this, the field must look beyond the traditional medical and social sciences to such disciplines as marketing science. Fourth, research designs that treat service providers as research subjects require careful consideration to ensure the protection of human subjects that have not been traditionally addressed by institutional review boards.

Finally, major challenges exist in the juxtaposition of the comparatively slow progress of science with the needs of practitioners, planners, administrators, and policymakers, who must respond quickly to the needs of patients and systems of care. The Recovery After an Initial

Schizophrenia Episode (RAISE) project of the NIMH provides a current example of a multidimensional partnership serving to hasten the translation of scientific findings to practice. The NIMH funded two RAISE projects to study the effectiveness and implementation of evidence-based, coordinated specialty care programs for young adults experiencing the onset of nonaffective psychosis. Attention to policy and practice while these research studies were being conducted led to the relatively rapid expansion of resources for evidence-based programs as part of the mental health block grant in 2014. For health services research to remain relevant, new models of partnership will continue to be needed—models that provide timely information in an iterative and collaborative manner among all stakeholders.
